Heterogeneous integration of novel dielectrics and novel channel materials has recently gained increasing attention as a necessity to further drive Si complementary metal-oxide-semiconductor (CMOS) integration, functional density, speed and power dissipation, and to extend CMOS front-end fabrication to and beyond the 22 nm node. Using III-V compound semiconductors as conduction channels, to replace traditional Si or strained Si, is currently an active research frontier due to the excellent electrical properties of III-V compound semiconductors and the existence of a viable III-V industry for more than 30 years. The principal obstacle to III-V compound semiconductors rivaling or exceeding the properties of Si electronics has been the lack of high-quality, thermodynamically stable insulators on GaAs (or on III-V materials in general) that equal the outstanding properties of SiO₂ on Si, e.g., a mid-band gap interface-trap density (D_it) of ~10^{10}/cm²⋅eV. For more than four decades, the research community has searched for suitable III-V compound semiconductor gate dielectrics or passivation layers. The literature testifies to the extent of this effort, with representative currently active approaches including sulfur passivation, silicon interface control layers (Si ICLS) in situ molecular beam epitaxy (MBE) growth of Ga₂O₃₆(Gd₂O₃) ex situ atomic layer deposition (ALD) growth of Al₂O₃ and HfO₂, wet oxidation of InAlP, jet vapor deposition of Si₃N₄, and ALD or PVD of HfO₂+Si ICL.

In this letter, we report a completely different approach—GaAs metal-insulator-semiconductor field-effect-transistors (MISFETs) exhibiting excellent performance can be fabricated under mild conditions using simple equipment and very thin biomembrane-like self-assembled nanodielectrics (SANDs) as the insulating layer. Primarily developed for enhancing the response of organic thin-film transistors (OTFTs), self-assembled organic gate dielectrics can be deposited at room temperature via layer-by-layer solution phase techniques using organosilane precursors. This yields smooth, nanostructurally well-defined, strongly adherent, thermally stable, and pinhole-free, organosiloxane thin films exhibiting excellent insulating properties (leakage current densities as low as ~10⁻⁹ A/cm² with native SiO₂ on Si), a large single Stb layer (Fig. 1) capacitance (up to ~0.025 pF/μm²) and dielectric constant (k) of ~16, enabling OTFT function at very low operating voltages. These dielectrics exhibit good uniformity over areas as large as ~150 cm², are insoluble in common solvents, can be patterned using standard microelectronic etching methodologies, and adhere to/are compatible with a wide range of substrates. The work reported in this letter unambiguously demonstrates facile integration of SANDs with III-V compound semiconductors.

For the present GaAs MISFET devices (Fig. 1) we employed a 700−900 Å Si-doped (4×10¹⁷/cm³) GaAs layer as the channel and a 1500 Å C-doped (5×10¹⁵/cm³) GaAs buffer layer on a P+ GaAs substrate grown by metalorganic chemical vapor deposition (MOCVD). Device isolation was achieved by oxygen implantation. Activation annealing was performed at the same time as ohmic contact formation. Ohmic contacts were formed by e-beam deposition of Au/Ge/Au/Ni/Au structures and a lift-off process, followed by 400 °C annealing in an N₂ ambient. Prior to SAND deposition, hydrophilic or hydrophobic GaAs surfaces were prepared using NH₄OH or HCl pretreatments, respectively. The SAND growth process (see Fig. 1) was as follows: 5 mM Alk reagent in dry toluene at 0 °C in N₂ for 1 h; 34 mM Cap reagent in dry pentane at 25 °C in N₂ for 25 min; 10 mM Stb reagent in dry tetrahydrofuran at 60 °C in N₂ for 15 min, followed by hydrolysis with acetone-H₂O solution to yield a 5.5-nm-thick type III SAND film (Fig. 1). Finally, conventional Ti/Au structures were deposited by e-beam evaporation, followed by lift-off to form the gate electrodes.
The source-to-gate and the drain-to-gate spacings are \( \sim 1 \) \( \mu m \). The sheet resistance and contact resistance are 1.5–2.5 k\( \Omega \)/sq. (depending on the thickness of \( n \) channels) and 1.5 \( \Omega \) mm, respectively, measured using a transmission length method (TLM). The gate lengths of the measured devices are 0.5 and 1 \( \mu m \). The process requires four levels of lithography (alignment, isolation, ohmic and gate), all done using a contact printer.

Figures 2(a) and 2(b) illustrate 500 Hz–1 MHz \( C-V \) measurements on MIS capacitors fabricated with type III SAND layers (Fig. 1) as the insulator in parallel with the MISFETs. The results demonstrate the importance of the GaAs surface pretreatment (NH\(_4\)OH vs HCl) on the SAND/GaAs interface quality. Larger frequency dependent flatband shifts, frequency dispersions at accumulation capacitances, and hysteresis are observed for HCl-pretreated devices as shown in Fig. 2(b). Conversely, the NH\(_4\)OH pretreatment producing a hydroxylated GaAs surface results in high-quality SAND layers as demonstrated by the \( C-V \) measurements. Hydroxylated GaAs surfaces favor SAND chemisorption, hence passivation, since the Alk Si–Cl groups react with the GaAs surface OH groups to form strong, covalent bonds (see Fig. 1). More detailed studies of these processes are in progress. The typical hysteresis observed in these devices as shown in Fig. 2(a) is less than 80 \( \mu m \), corresponding to a slow trap density of about 2 \( \times 10^{11}/cm^2 \cdot eV \). Consequently, all of the MISFET \( I-V \) characteristics were measured on NH\(_4\)OH treated devices. The dielectric constant of the currently employed SAND is \( \sim 3.4 \) as obtained from \( C-V \) measurements. Systematic studies with different SAND variants having higher \( k \) values, different III-V surfaces, such as \( n \)-type or \( p \)-type GaAs, InGaAs, and GaN, different pre-deposition surface treatments and different device structures are currently in progress.

Figure 3(a) shows the gate leakage current density \( J_g \) versus gate bias \( V_g \) for SANDs deposited on hydroxylated GaAs with film thicknesses ranging from 5.5 nm [type III] to 16.5 nm [type III]. The 16.5-nm-thick SAND is realized by three successive depositions of a 5.5-nm-thick type III SAND film (Fig. 1). The corresponding gate leakage current of a MISFET having a 1 \( \mu m \) gate length and a 100 \( \mu m \) gate width is very small, 10 pA–10 nA, which is at least six orders of magnitude smaller than the drain current. The dielectric strength of this organic film is as high as 6 MV/cm, comparable to conventional inorganic gate dielectrics such as SiO\(_2\), Si\(_3\)N\(_4\) or HIO\(_2\). The small SAND leakage currents and large breakdown strengths are attributed to the heavily three-dimensional cross-linked structures, containing dense arrays of strong Si–O bonds and polarizable \( \pi \)-electron spacers.\(^{1,16}\)

Figure 3(b) shows the \( I-V \) characteristics for a 0.5 \( \mu m \)-gate-length GaAs MISFET with a 5.5-nm-thick type III SAND film. The 800-\( \AA \)-thick MOCVD GaAs channel layer leads to a maximum drain current of 280 mA/mm with a pinch-off voltage of \( \sim 2.5 \) V. A parasitic resistance of 4 \( \Omega \) mm is obtained from the resistance of the mobility region in Fig. 3(b). The same number can also be calculated from the measured sheet resistance of 2.5 k\( \Omega \)/sq. and contact resistance of 1.5 \( \Omega \) mm from the TLM measurement, using a gate-source spacing of 1 \( \mu m \). The maximum intrinsic transconductance, \( g_m \), is \( \sim 170 \) mS/mm for \( L_g \) = 0.5 \( \mu m \) as shown in Fig. 3(c). Such large transconductance values indicate that the interface trap densities are remarkably low. The \( I-V \) characteristics for a 1 \( \mu m \)-gate-length GaAs MISFET with a 16.5-nm-thick SAND are shown in Fig. 3(d). The maximum drain current density at a forward gate bias of 2 V is increased to \( \sim 370 \) mA/mm by employing a 900-\( \AA \)-thick MOCVD GaAs \( n \)-channel layer. The device is still cleanly pinched off at a gate bias of \( \sim 3.5 \) V, although the insulator layer is 16.5 nm thick. The maximum intrinsic transconductance is \( \sim 125 \) mS/mm by correcting for the parasitic resistance of 3 \( \Omega \) mm. Note that this result does not
scale with dielectric thickness due to depletion-mode operation, interface trap density, and incomplete electron velocity saturation. The estimated electron mobility from the maximum transconductances measured on 20-µm-long channel devices is $\sim 1875 \, \text{cm}^2/\text{V} \, \text{s}$, which is about a factor of 4–5 larger than the mobility in Si-based devices. The relatively large differences in drain current vs channel layer physical thickness, i.e., 370 vs 280 mA/mm for 900 vs 800 Å, is due to some depletion from C-doped $(5 \times 10^{16}/\text{cm}^3)$ p-type buffer layer on a P+ GaAs substrate.

In conclusion, we have demonstrated the implementation of SAND nanodielectrics for fabrication of GaAs MISFETs exhibiting excellent transistor characteristics. These results suggest more opportunities for manipulating the complex GaAs surface chemistry with unprecedented materials options and using organic dielectrics for high-performance III-V semiconductor devices. The SAND process is flexible, low-cost, and far simpler to implement than previously reported MBE or ALD dielectric deposition processes.
