Abstract

A new class of multiscale stochastic processes called spatial random trees (SRTs) is introduced and studied. As with previous multiscale stochastic processes, SRTs model multidimensional signals using random processes on trees. Our key innovation, however, is that the tree structure itself is random and is generated by a probabilistic context-free grammar (PCFG) [26]. While PCFGs have been used to model 1-D signals, the generalization to multiple dimensions is not direct because the leaves of a tree generated by a PCFG cannot be naturally mapped to a multidimensional lattice. We solve this problem by defining a new class of PCFGs which can produce trees whose leaves are naturally arranged in a multidimensional lattice. We call such trees admissible and show that each of them generates a unique multidimensional signal. Based on this framework, procedures are developed for likelihood calculation, MAP estimation of the processes, and parameter estimation. The new framework is illustrated through simple detection problems.

I. INTRODUCTION

In this work, we develop a new class of multiscale stochastic models for multidimensional signals, called spatial random trees (SRTs). Similar to [5, 6, 18], our models are stochastic processes on trees with each leaf corresponding to a single sample, for example, to a 2-D image pixel or a 3-D image voxel.\(^1\) Our key innovation, however, is that the tree structure itself is random and is generated by a probabilistic context-free grammar (PCFG) [26]. While PCFGs have been used to model 1-D signals [19], the generalization to multiple dimensions is not direct because the leaves of a tree generated by a PCFG cannot be naturally mapped to a multidimensional grid. We solve this problem by defining a new class of PCFGs which can produce trees whose leaves are naturally arranged in a multidimensional grid. We call such trees admissible and show that each of them generates a unique multidimensional signal.

PCFGs have been widely used in natural-language processing, for example, to model the structure of sentences [19]. The concept of a PCFG is based on the notion of branching stochastic processes which have been used in studying population dynamics since 1845 [4, 13, 14, 28]. These problems have been posed either in 1-D where the objects under consideration, for example, words in sentences, have a natural linear arrangement; or even in “0-D” where the arrangement of objects, such as molecules of

\(^1\)More generally, leaves may correspond to other observable quantities associated with a signal. This generalization will be considered elsewhere.
different types in a population of particles, does not matter. In addition to early efforts to apply both
deterministic grammars (see, e.g., [10, 25, 27], and references therein) and probabilistic grammars [10] in
2-D, probabilistic grammars have more recently been applied to such 2-D problems as optical character
recognition [23] and analyzing the layout of document images [12].

These developments have motivated the formulation of SRTs–our new general framework for model-
ing multidimensional signals with PCFGs. This framework is described in Section III and is the central
contribution of this paper. We explain in Section VI that fixed-tree multiscale stochastic models, such as
[5, 6], are a special case of our model. In general, however, instead of imposing a fixed multiscale tree
structure on a signal, our model is able to adapt its tree structure to data.

For the sake of clarity, we keep most of our exposition of SRTs in this paper to 2-D; we only sketch the
generalizations of our definitions and results to an arbitrary number of dimensions since these generaliza-
tions are straightforward. A key reason for the applicability of our results to any number of dimensions
is that the underlying tree structure is always a binary tree, regardless of the number of dimensions.

Once our framework is in place, we obtain exact recursive algorithms for computing likelihoods and
for finding the MAP estimate of the tree structure and the corresponding states, as well as adapt the
Baum-Welch (or EM) algorithm [3] to the training problem, i.e., the problem of searching for the pa-
rameter values for our model that maximize the likelihood function. We collectively term these resulting
algorithms the Center-Surround algorithm. They form the second major contribution of this paper. They
are a generalization of–and were inspired by–the Forward-Backward algorithm [24] for hidden Markov
models and the Inside-Outside algorithm [1, 16, 19] for 1-D PCFGs.

Even though the core of this paper is theoretical, we also include simulation results since we believe
that the major impact of our framework will eventually be in the area of applications. While extensive
experiments with real data are certainly beyond the scope of this paper, we do include simple synthetic ex-
amples in Section V to illustrate the Center-Surround algorithm. Research efforts are currently underway
to adapt our method to several practical application domains.

The organization of our paper is as follows. The background on branching processes and PCFGs
in 1-D is provided in Section II. Although this section is mostly tutorial, we believe that our approach
to defining a probability distribution on the set of trees associated with a branching process is simpler
than previous approaches in [9, 11, 21]. In Section III, we introduce spatial random trees. Section IV
discusses inference using SRTs. Specifically, Subsection IV-A introduces exact recursive algorithms for
calculating the probability of a multidimensional signal; Subsection IV-B describes an exact recursive
algorithm which computes the best parse for a multidimensional signal, that is, it extracts the maximum a posteriori probability tree whose leaves are signal samples; and Subsection IV-C is devoted to training our model through the EM algorithm. Section V presents our experimental examples. Section VI places our framework in the context of the existing research and describes our current research directions.

II. BACKGROUND

A. Branching Processes and PCFGs

Following [9, 15, 21], we consider a population of objects (for example, particles or people’s surnames or grammatical structures) of several terminal types and nonterminal types. Objects of any nonterminal type are capable of reproducing whereas terminal objects are not. We assume that both the set $T$ of all possible terminal types and the set $N$ of all possible nonterminal types are finite sets. We consider a discrete-time process of evolution of the population of objects, with time indexed by the set of all nonnegative integers. We suppose that at each time step one object of nonterminal type $j$ is either transformed into two objects of nonterminal types $k$ and $\ell$ with probability $P_{\text{prod}}(j \rightarrow k, \ell)$, or into one object of terminal type $u$ with probability $P_{\text{prod}}(j \rightarrow u)$. In keeping with the terminology from formal language theory [26], we call each allowed transformation a production rule:

$$
\begin{align*}
  j &\rightarrow k, \ell \quad \forall j, k, \ell \in N, \\
  j &\rightarrow u \quad \forall j \in N, \forall u \in T.
\end{align*}
$$

Rules (1) are called nonterminal production rules, and rules (2) are called terminal production rules. The set of all production rules is denoted $\mathcal{P}$ and the triple $(N, T, \mathcal{P})$ consisting of the sets of nonterminal and terminal types and the set of production rules is an example of what is called a context-free grammar in formal language theory [19]. (We assume here that $\mathcal{P}$ is uniquely determined by $N$ and $T$ via Eqs. (1,2).)

We use $\mathcal{P}^j$ to denote the set of all production rules which have state $j$ in the lefthand side. The production probabilities must satisfy the following normalization equations:

$$
\sum_{\Lambda \in \mathcal{P}^j} P_{\text{prod}}(\Lambda) = 1, \quad \forall j \in N,
$$

which say that any object of a nonterminal type gets transformed into something (either a pair of nonterminal objects or a single terminal object) with unit probability.

We further assume that initially, at time 0, there exists just one object whose type is $j \in N$ with probability $P_{\text{root}}(j)$ where this initial probability distribution $P_{\text{root}}$ must also satisfy a normalization
property:
\[ \sum_{j \in \mathbb{N}} P_{\text{root}}(j) = 1. \]  

(4)

This stochastic process of transformations of our objects is easily seen to be a branching process, defined in, e.g., [11, 15]. (The term multiplicative process has also been used, e.g., in [9, 21].) The corresponding context-free grammar, equipped with probability distributions \( P_{\text{root}} \) and \( P_{\text{prod}} \), is called in natural-language processing [19] a probabilistic (or stochastic) context-free grammar (PCFG or SCFG).

We consider the set of all possible genealogies, i.e., the set of all records of the transformations of the initial object (generation 0) and its descendants (generations 1, 2, ...). We represent a genealogy as a (deterministic) tree, by drawing a dot with “\( j \)” next to it for every object of type \( j \), and connecting every object to its children, that is, to the objects it gets transformed into, as in Fig. 1. We moreover observe the convention of drawing the children below their parent. In our discussion of trees, we adopt the standard terms [8] vertex which is synonymous with a dot representing one of our objects, and edge which denotes any parent-child pair. We use lowercase Greek letters to index the vertices of trees, with \( \rho \) exclusively denoting the root vertex, that is, the vertex corresponding to the original object at time 0. The type of the object corresponding to vertex \( \alpha \) is called the state at \( \alpha \) and is denoted by \( x_\alpha \). A tree is therefore a triple \((\mathcal{V}, \mathcal{E}, x)\) consisting of a set \( \mathcal{V} \) of all vertices, a set \( \mathcal{E} \) of all edges, and a mapping \( x \) from \( \mathcal{V} \) to \( \mathbb{N} \cup \mathcal{T} \) which associates a state (type) \( x_\alpha \) to every vertex (object) \( \alpha \).

We conclude this subsection by describing some other terms and notational conventions pertaining to trees which will be used in the remainder of the paper. (See Table II in the Appendix for a concise summary of our notation.) We say that a tree has depth \( i \) if it consists of generations 0, 1, ..., \( i \). It is sometimes convenient to abbreviate a generic production rule as \( \Lambda \) (this was done in Eq. (3) above), and to denote the production rule applied at a vertex \( \alpha \) as \( \Lambda_\alpha \). For example, referring to the tree of Fig. 1(a), \( \Lambda_\rho \)--meaning the production rule applied at the root vertex--is in this case simply a shorthand for \( j \rightarrow j, j \).

For any vertex \( \alpha \) that has two children, we always assume that the children are ordered, and denote the first child as \( C_1(\alpha) \) and the second child as \( C_2(\alpha) \). A vertex which has at least one child is called an internal vertex, and a vertex with no children is called a leaf. The yield of any internal vertex \( \alpha \), denoted \( \mathcal{Y}(\alpha) \), is the set of all leaf descendants of \( \alpha \). Alternatively, we say that \( \alpha \) dominates \( \mathcal{Y}(\alpha) \), and write \( \alpha = \mathcal{Y}^{-1}(\mathcal{Y}(\alpha)) \). For a set which is not the yield of an internal vertex, the inverse yield function \( \mathcal{Y}^{-1} \) is not defined. The yield of a leaf is undefined since we do not consider any vertex to be a descendant of itself. The yield of a tree is synonymous with the yield of the root of the tree.
(a) An $\Omega$-tree of depth 2. (b) An $\Omega$-tree of infinite depth. (c) A 1-pruned tree.

Fig. 1. (a,b) Two $\Omega$-trees generated by applying two rules ($j \rightarrow j, j$ and $j \rightarrow u$) of the PCFG in Eqs. (1,2). (c) A 1-pruned tree generated by the same PCFG.

B. Probability Distribution on the Set of Trees

Our basic strategy for defining a probability distribution on the set of all trees is similar to [9, 11, 21]: we first define probability distributions on sets of finite-depth trees, and then extend them to the set of all trees. The set of all possible trees that can be generated by a PCFG $\mathcal{G}$ is denoted by $\Omega(\mathcal{G})$. Throughout this paper, it is always clear from context which PCFG is being discussed, and therefore we will call this set $\Omega$ for brevity. While the elements of $\Omega$ are simply trees, we will also sometimes call them $\Omega$-trees, in order to avoid confusion with $i$-pruned trees. The process of $i$-pruning can be applied to an $\Omega$-tree whose depth is strictly greater than $i$, and simply means retaining only generations $0, 1, \ldots, i$ of the $\Omega$-tree and discarding the remaining generations. The resulting tree is called an $i$-pruned tree. The process of $i$-pruning can moreover be applied to any $i'$-pruned tree to obtain an $i$-pruned tree if $i' > i$. For example, the 1-pruned tree in Fig. 1(c) results if we retain only generations 0 and 1 of the $\Omega$-tree of Fig. 1(a) or (b). The result of 0-pruning the 1-pruned tree of Fig. 1(c) would be a 0-pruned tree of depth 0 consisting of a single root vertex with state $j$.

The equivalence class of all $\Omega$-trees whose $i$-pruning results in a given $i$-pruned tree $T$ is denoted by $[T]$. If $T$ is an $\Omega$-tree, we denote $[T] = T$.

We use $\Pi_i(\mathcal{G})$ (or simply $\Pi_i$) to denote the set of all $i$-pruned trees. For example, one element of the set $\Pi_1$ for the PCFG in Eqs. (1,2) is depicted in Fig. 1(c). We use $\Phi_i(\mathcal{G})$ (or simply $\Phi_i$) to denote the set of all $\Omega$-trees whose depth is $i$. We use $\Omega_i$ to denote the set consisting of all $\Omega$-trees of depth $i$ or smaller, and all $i$-pruned trees:

$$\Omega_0 = \Pi_0; \quad \Omega_i = \bigcup_{i'=1}^{i} \Phi_{i'} \cup \Pi_i \quad \text{for } i = 1, 2, \ldots$$

If $i' > i$, the equivalence class of all trees in $\Omega_{i'}$ whose $i'$-pruning results in a given $i$-pruned tree $T$ is
denoted by \([T]_i\).

We first define a probability distribution \(P_i\) on the set \(\Omega_i\), and then extend it to \(\Omega\). The probability of any tree \(T \in \Omega_i\) is defined to be the product of the root state probability and the probabilities of all the production rules that are involved in generating \(T\):

\[
P_i(T) \overset{\Delta}{=} P_{\text{root}}(x_\rho) \prod_{\alpha \in \mathcal{V}_{\text{int}}} P_{\text{prod}}(\Lambda_\alpha),
\]

(5)

where \(\rho\) is the root vertex of \(T\), \(\mathcal{V}_{\text{int}}\) is the set of all internal vertices of \(T\), and \(\Lambda_\alpha\) is the production rule applied at \(\alpha\). We now need two auxiliary results which will be used throughout the remainder of the paper, and in particular, in the main propositions of this subsection. For any \(\Omega\)-tree of depth \(i\), definition (5) is consistent: \(P_i(T) = P_i(T')\) for any \(i' > i\). We now show that definition (5) is moreover consistent for \(i\)-pruned trees, in the sense that the probability of any \(i\)-pruned tree \(T\) as defined by Eq. (5) is the same as the probability of the corresponding equivalence class \([T]_i\), for any \(i' > i\).

**Lemma 1.** If \(T \in \Omega_i\) and \(i' > i\) then \(P_{i'}([T]_i) = P_i(T)\).

**Proof.** See Appendix. ■

To show that \(P_i\) is indeed a probability distribution on \(\Omega_i\), we need the following lemma which says that \(P_{\text{root}}(j)\) is equal to the combined probability of the set of all \(\Omega\)-trees of depth \(i\) or smaller whose root state is \(j\) and the set of all \(i\)-pruned trees whose root state is \(j\).

**Lemma 2.** Let \(\Omega_i^j\) be the set of all trees in \(\Omega_i\) whose root state is \(j\). Then

\[
P_i(\Omega_i^j) = P_{\text{root}}(j).
\]

(6)

**Proof.** See Appendix. ■

**Proposition 1.** \(P_i(\Omega_i) = 1\).

**Proof.** It follows from the definition of \(\Omega_i^j\) that \(\Omega_i = \bigcup_{j \in \mathcal{N}} \Omega_i^j\) and that the sets \(\{\Omega_i^j\}_{j \in \mathcal{N}}\) are mutually disjoint. Therefore, by Lemma 2 and normalization equation (4), we have:

\[
P_i(\Omega_i) = \sum_{j \in \mathcal{N}} P_i(\Omega_i^j) = \sum_{j \in \mathcal{N}} P_{\text{root}}(j) = 1. \quad \Box
\]

Our function \(P_i\) is thus a probability distribution on \(\Omega_i\), for any \(i\). We now extend it to \(\Omega\).

For any subset \(A\) of \(\Omega_i\), we let \([A]\) be the induced subset of \(\Omega\):

\[
[A] = \bigcup_{T \in A} [T] \quad \text{for any } A \subset \Omega_i.
\]
For any collection $\mathcal{A}$ of subsets of $\Omega$, we let $[\mathcal{A}]$ be the induced collection of subsets of $\Omega$:

$$[\mathcal{A}] = \bigcup_{A \in \mathcal{A}} \{[A]\}.$$  

We let $\mathcal{A}_i$ be the power set of $\Omega_i$, i.e., the collection of all subsets of $\Omega_i$. The following lemma constructs an algebra of subsets of $\Omega$ and extends $P_i$ to a probability measure on the algebra.

**Lemma 3.** Let $\mathcal{A}_\infty = \bigcup_{i=0}^{\infty} [\mathcal{A}_i]$ be the collection of subsets of $\Omega$ induced by all the subsets of all the $\Omega_i$’s.

(i) Then $\mathcal{A}_\infty$ is an algebra (i.e., it is closed under set complementation and finite union).

(ii) For any $[A] \in \mathcal{A}_\infty$, define

$$\widetilde{P}(\{A\}) \overset{\Delta}{=} P_i(A),$$

where $i$ is such that $A \in \mathcal{A}_i$. Then $\widetilde{P}$ is a probability measure on $\mathcal{A}_\infty$.

**Proof.** See Appendix.

In order to get a legitimate probability measure, it only remains to extend our algebra $\mathcal{A}_\infty$ to a $\sigma$-algebra.\(^2\)

The following proposition is a direct corollary of Lemma 3 and the extension theorem (page 23 of [20]) which says that any probability measure on an algebra can be uniquely extended to the smallest $\sigma$-algebra which contains that algebra.

**Proposition 2.** Let $\mathcal{A}$ be the smallest $\sigma$-algebra containing $\mathcal{A}_\infty$. There exists a unique probability measure $P$ defined on $\mathcal{A}$ such that the restriction of $P$ to $\mathcal{A}_\infty$ is $\widetilde{P}$.

This proposition says that we have defined a probability distribution $P$ on $\Omega$, with probabilities of $\Omega$-trees and $i$-pruned trees given by $P_i$ of Eq. (5).

### III. Spatial Random Trees

#### A. Notation for Multidimensional Signals

While our results below generalize to an arbitrary number of dimensions, we primarily consider 2-D signals—which we call images—whose domain of definition is an $M_1 \times M_2$ rectangle, as illustrated in Fig. 2. In other words, an image $u$ is just an $M_1 \times M_2$ matrix of numbers. The rectangular domain whose upper left corner is $p = (p_1, p_2)$ and whose lower right corner is $q = (q_1, q_2)$ is denoted $\Box_{pq}$. If $q_1 < p_1$ or $q_2 < p_2$ then $\Box_{pq}$ simply denotes an empty rectangle. For $p = (p_1, p_2)$, we write $u_p$ and \(\Box_{pq}\) simply denotes an empty rectangle. For $p = (p_1, p_2)$, we write $u_p$ and

\(^2\)A $\sigma$-algebra is an algebra which is closed under countable union [20].
Fig. 2. An illustration of our notation for images defined on an \( M_1 \times M_2 \) rectangular grid.

\[ \square_{pp} = \square_{p} = p \] to denote the value and location, respectively, of the pixel at the intersection of row \( p_1 \) and column \( p_2 \). We abbreviate \( \mathbf{1} = (1, 1) \) and \( M = (M_1, M_2) \), so that the whole domain of definition of image \( u \) is \( \square_{1,M} \).

For an arbitrary number of dimensions \( D \), our signal is a \( D \)-dimensional \( M_1 \times \ldots \times M_D \) matrix, and the domain \( \square_{pq} \) is defined by its two corner points \( p = (p_1, \ldots, p_D) \) and \( q = (q_1, \ldots, q_D) \).

B. SRT: Definition

Finite \( \Omega \)-trees illustrated in Fig. 1(a) can be used to model linearly arranged objects such as words which form sentences, each word being the state of a leaf. The set of all leaves \( \mathcal{Y}(\rho) \) has a natural arrangement, from left to right. The yield of each internal vertex of such a tree is a contiguous segment in \( \mathcal{Y}(\rho) \); moreover, if \( \beta \) and \( \gamma \) are the children of \( \alpha \) then \( \mathcal{Y}(\beta) \) and \( \mathcal{Y}(\gamma) \) are nonoverlapping segments whose union is \( \mathcal{Y}(\alpha) \).

In order to model images, the yield of an \( \Omega \)-tree must be capable of representing pixels arranged in an \( M_1 \times M_2 \) rectangular grid. In our framework, the yield \( \mathcal{Y}(\alpha) \) of each internal vertex \( \alpha \) of the resulting tree is a nonempty rectangular region of an image, with each leaf representing a \( 1 \times 1 \) region, i.e., a single pixel location. If \( \beta \) and \( \gamma \) are the children of \( \alpha \) then \( \mathcal{Y}(\beta) \) and \( \mathcal{Y}(\gamma) \) are nonoverlapping rectangular regions whose union is \( \mathcal{Y}(\alpha) \).

A key innovation that makes this possible is to have two different kinds of nonterminal production rules: horizontal, to represent top-bottom splits; and vertical, to represent left-right splits. Specifically, an application of a horizontal nonterminal production rule splits the rectangular region \( \mathcal{Y}(\alpha) \) into a top subrectangle \( \mathcal{Y}(\beta) \) and a bottom subrectangle \( \mathcal{Y}(\gamma) \) where \( \beta = C_1(\alpha) \) and \( \gamma = C_2(\alpha) \). An application
of a vertical nonterminal production rule splits the rectangular region $Y(\alpha)$ into a left subrectangle $Y(\beta)$ and a right subrectangle $Y(\gamma)$ where, again, $\beta = C_1(\alpha)$ and $\gamma = C_2(\alpha)$. We use $O$ to denote the set of possible orientations of a nonterminal production rule: $O = \{h, v\}$. Our basic 1-D PCFG of Eqs. (1,2) is modified as follows:

$$j \xrightarrow{a} k, \ell \forall j, k, \ell \in \mathcal{N}, \forall o \in O,$$

$$j \rightarrow u \forall j \in \mathcal{N}, \forall u \in T. \tag{7} \tag{8}$$

Our definition of a tree $T = (\mathcal{Y}, \mathcal{E}, x, o)$ now includes a function $o$ from the vertex set to the set $O$ of orientations. For any vertex $\alpha$ with two children, $o_\alpha$ is the orientation of the production rule applied at $\alpha$.

The generalization to $D$ dimensions is straightforward: the set $O$ then has $D$ elements, $O = \{i_1, \ldots, i_D\}$, and there are $D$ corresponding varieties of nonterminal production rules: $j \xrightarrow{i_d} k, \ell$ for $d = 1, \ldots, D$. It is important to emphasize here that, regardless of the number of dimensions, our basic modeling structure is a binary tree, i.e., a tree where each vertex has at most two children, due to the fact that the righthand side of a nonterminal production rule always has two elements. This property is in contrast with [5,6,18] where images are modeled with quadtrees.

C. Generating Images from the PCFG of Eqs. (7,8)

We have not yet specified precisely what it means for the yield of an $\Omega$-tree produced by our PCFG to form an $M_1 \times M_2$ rectangular grid. Indeed, each production rule only specifies the orientation of a split of a rectangular domain (horizontal with $o = h$ in Eq. (7) or vertical with $o = v$ in Eq. (7)), but does not
specify exactly where the split will occur. It is moreover undesirable to fix the sizes of the rectangular regions a priori—in other words, we do not want to require the state of an internal vertex of an \(\Omega\)-tree to contain information about the size of its yield. Otherwise, our model would become unmanageable since there would be an enormous number of possible states and production rules even for images of moderate size. At first glance, it may therefore seem that our PCFG is too ill-defined to unambiguously generate regularly sampled images. We now show that this is not the case. We start with an example.

**Example 1.** We let \(T = \{1, 2, 3, 4, 5, 6\}\) and construct an \(\Omega\)-tree by letting the root state be \(j\) and applying the following sequence of production rules:

\[
\begin{align*}
  j &\rightarrow_h j; j \text{ at the root vertex }\rho; \\
  j &\rightarrow_v j; j \text{ both at }\sigma = C_1(\rho) \text{ and at }\tau = C_2(\rho); \\
  j &\rightarrow 1 \text{ at }C_1(\sigma); \quad j &\rightarrow 6 \text{ at }C_2(\tau); \\
  j &\rightarrow u \text{ for }u = 2, 3, 4, 5, \text{ at the remaining internal vertices.}
\end{align*}
\]

This results in the tree depicted in Fig. 3(a). As shown in Fig. 3(b), this tree generates a \(2 \times 3\) image. The yield of each internal vertex \(\alpha\) of the tree is a nonempty rectangular region \(Y(\alpha)\). The root corresponds to the whole image domain—i.e., \(Y(\rho)\) is the whole \(2 \times 3\) domain of definition of our image. Moreover, each application of a nonterminal production rule involves splitting a rectangular region \(Y(\alpha)\) into two other nonempty rectangular regions, \(Y(C_1(\alpha))\) and \(Y(C_2(\alpha))\). The orientation of the splitting is either horizontal or vertical, and is specified by the orientation of the nonterminal production rule.

A horizontal split at a vertex \(\alpha\) is denoted in our diagrams with a horizontal line through the vertex. For example, the \(2 \times 3\) image domain corresponding to the root vertex \(\rho\) in Fig. 3(b) is split horizontally, to result in the first child \(\sigma = C_1(\rho)\) whose yield is the top \(1 \times 3\) subrectangle, and the second child \(\tau = C_2(\rho)\) whose yield is the bottom \(1 \times 3\) subrectangle.

A vertical split at a vertex \(\alpha\) is denoted in our diagrams with a vertical line through the vertex. For example, the \(1 \times 3\) rectangle which is the yield of the first child \(\sigma\) of the root vertex in Fig. 3(b) is split vertically, to result in the first child \(C_1(\sigma)\) whose yield is the top left pixel, and the second child \(C_2(\sigma)\) whose yield is the rectangular region with pixel values 2, 3.

It is not always the case that the yield of an \(\Omega\)-tree can be bijectively mapped to an \(M_1 \times M_2\) rectangular grid. For example, the tree of Fig. 4(a) does not correspond to such a grid, as illustrated in Fig. 4(b). Regardless of the locations of splits, the first row will have two “pixels” whereas the second and third row will have only one “pixel” each. We call such \(\Omega\)-trees *inadmissible trees*. The trees for which there exists
Fig. 4. (a) An \( \Omega \)-tree that does not correspond to an \( M_1 \times M_2 \) rectangular grid. (b) Regardless of the split locations, the first row will have two “pixels” whereas the second and third rows will have only one “pixel” each.

A bijective association between the leaves and pixel locations on a rectangular grid, are called \textit{admissible}.

\textbf{Definition 1 (Admissible trees).} Let \( T \) be an \( \Omega \)-tree generated by the PCFG of Eqs. (7,8). Let \( \mathcal{V}_{\text{int}} \) be the set of its internal vertices, and let \( \rho \) be its root vertex. Suppose that there exist a pair of positive integers \( M = (M_1, M_2) \) and a bijective function 

\[ \mathcal{F} : \mathcal{Y}(\rho) \rightarrow \square_{M_1 M_2} \]

which uniquely maps each leaf of the tree to a location in an \( M_1 \times M_2 \) grid, and which has the following property: the yield of each internal vertex of the tree is mapped to a rectangular region, i.e.,

\[ \forall \alpha \in \mathcal{V}_{\text{int}} \; \exists p, q \text{ such that } \{ \mathcal{F}(\beta) | \beta \in \mathcal{Y}(\alpha) \} = \square_{pq}. \]

We then say that \( T \) is an \textit{admissible tree} and \( \mathcal{F} \) is an associated admissibility function.

We now show that, if the yield of an \( \Omega \)-tree can be mapped to an image grid in a manner described above and illustrated in Fig. 3, such mapping is unique.

\textbf{Theorem 1 (Admissibility Theorem).} If a tree \( T \) is admissible, there is a unique admissibility function for \( T \).

\textbf{Proof.} We denote the leaves of \( T \), ordered left to right, by \( \lambda_1, \ldots, \lambda_I \). Our proof is a recursive procedure which constructs \( \mathcal{F}(\lambda_1), \ldots, \mathcal{F}(\lambda_I) \) from left to right. If the procedure fails, the tree is inadmissible; we show, however, that if the procedure succeeds, then it constructs a unique \( \mathcal{F} \).

For any internal vertex \( \alpha \), we use the following notation:

\[ \mathcal{F}(\alpha) = \{ \mathcal{F}(\beta) | \beta \in \mathcal{Y}(\alpha) \}, \]

meaning that \( \mathcal{F}(\alpha) \) is the rectangular region (9) into which the yield of \( \alpha \) is mapped by the function \( \mathcal{F} \).
Our proof is inductive; both the base of the induction and the induction step are obtained from the following observation which immediately follows from our definition of nonterminal production rules: the leftmost leaf of the yield of an internal vertex $\gamma$ must be the upper left corner of $\mathcal{F}(\gamma)$. In other words, suppose that vertex $\gamma$ has yield $\lambda_{\text{left}}, \ldots, \lambda_{\text{right}}$ and that $\mathcal{F}(\gamma) = pq$. Then $\mathcal{F}(\lambda_{\text{left}}) = p$.

This observation implies that $\mathcal{F}(\lambda_1) = 1$, which is the base of our induction.

Suppose now that $\mathcal{F}(\lambda_1), \ldots, \mathcal{F}(\lambda_i)$ have been uniquely determined. We now show that either $\mathcal{F}(\lambda_{i+1})$ is undefined (in which case the tree $T$ is inadmissible), or it can be determined uniquely.

Suppose that $\alpha$ is the youngest common ancestor of $\lambda_i$ and $\lambda_{i+1}$, that is, $\alpha$ is an ancestor of both $\lambda_i$ and $\lambda_{i+1}$ and none of the children of $\alpha$ is an ancestor of both $\lambda_i$ and $\lambda_{i+1}$. Let $\beta = C_1(\alpha)$ and $\gamma = C_2(\alpha)$ be the first and second child of $\alpha$, respectively. By construction, the rightmost vertex of the yield of $\beta$ is $\lambda_i$, and so the yield of $\beta$ is a subset of $\{\lambda_i, \ldots, \lambda_i\}$. Thus $\mathcal{F}(\beta)$ has been uniquely determined. Let us denote $\mathcal{F}(\beta) = pq$. Furthermore, let $m$ be the number of vertices in the yield of $\gamma$.

As shown in Fig. 5(a), if $x_\alpha \xrightarrow{h} x_\beta, x_\gamma$, then, by our definition of a horizontal nonterminal production rule, there must exist an integer $e$ such that

$$\mathcal{F}(\gamma) = \square_{(q_1+1,p_2),(e,q_2)},$$

i.e., the yield of $\gamma$ must correspond to a rectangle with $q_2 - p_2 + 1$ columns. Therefore, if the number $m$ of leaves in the yield of $\gamma$ is not divisible by $q_2 - p_2 + 1$, we immediately have that the tree $T$ is inadmissible. If, however, $m$ is divisible by $q_2 - p_2 + 1$, we know that the leftmost leaf in the yield of $\gamma$
must correspond to the upper left corner of $\Box_{(q_1+1, p_2), (e, q_2)}$:

$$\mathcal{F}(\lambda_{i+1}) = \Box_{(q_1+1, p_2)}.$$ 

Similarly, if $x_\alpha \xrightarrow{u} x_\beta, x_\gamma$, then, by our definition of a vertical nonterminal production rule, there must exist an integer $e$ such that

$$\mathcal{F}(\gamma) = \Box_{(p_1, q_2+1), (q_1, e)}.$$

This is illustrated in Fig. 5(b). In this case, if $m$ is not divisible by $q_1 - p_1 + 1$, then the tree is inadmissible; otherwise,

$$\mathcal{F}(\lambda_{i+1}) = \Box_{(p_1, q_2+1)}.$$ 

This completes our induction. 

We note that while the Admissibility Theorem is stated and proved in 2-D, it also holds for an arbitrary number of dimensions. This identification of the leaves of an admissible tree with pixel locations in an $M_1 \times M_2$ (or, more generally, $M_1 \times \ldots \times M_D$) rectangular grid justifies the terminology we used in Example 1, allowing us to identify $\mathcal{Y}(\alpha)$ with $\Box_{pq}$ for any internal vertex $\alpha$ of an admissible tree with $\mathcal{F}(\alpha) = \Box_{pq}$.

D. Probability Model

Since our PCFG of Eqs. (7,8) is similar to Eqs. (1,2), we can define a probability distribution on the set of all $\Omega$-trees generated by this PCFG, via a procedure similar to that of Subsection II-B.

Suppose now that we have an $M_1 \times M_2$ image $u = u_{1,M}$ and an admissible tree $T$. If the yield of $T$ is $\Box_{1,M}$ and the states of the leaves are $u_{1,M}$, we say that the tree $T$ generates the image $u$. We define an event\(^3\) $\Omega_u$ to be the set of all admissible trees that generate the image $u$. The term probability of an image $u$, denoted $P(u)$, is shorthand for the probability of the set $\Omega_u$. Note that $P(u)$ does not, in general, define a probability distribution on the set of all images since the set of all admissible trees does not, in general, have unit probability. A probability distribution $P'$ on the set of images can be obtained by conditioning on the set of admissible trees:

$$P'(u) = \frac{P(u)}{\sum_{u'} P(u')}.$$ 

The probability $P'(u)$ is, in general, very difficult to compute because of the denominator in the expression (12). Fortunately, we will not need to compute it in any of the algorithms developed below.

\(^3\)We emphasize here that our notation $\Omega_u$ has no relation to the notation $\Omega_i$ which we used in Section II.
Definition 2. The stochastic process defined by the PCFG \( G \) of Eqs. (7,8), with a probability distribution on \( \Omega(G) \) as defined above, and with the ensuing probabilities of images, is called a spatial random tree (SRT).

IV. SRTs AND INFERENCE: THE CENTER-SURROUND ALGORITHM

Within our framework of spatial random trees, we pose three basic problems as suggested by [24]:

- **Likelihood computation.** Given a PCFG \( G \), find the likelihood \( P(u|G) \) of the data \( u \).
- **MAP estimation of a tree.** Find the most probable tree for the data \( u \),
  \[
  \arg \max_{T \in \Omega} P(T|\Omega_u).
  \]
- **ML parameter estimation.** Choose a PCFG \( G \) that maximizes the likelihood\(^4\) of an observation \( u \) or a sequence of observations \( u^1, \ldots, u^I \):
  \[
  \arg \max_G P(u^1, \ldots, u^I|G).
  \]

We address these three problems in subsections IV-A, IV-B, and IV-C, respectively. The algorithms that we develop are collectively termed the **Center-Surround Algorithm** and are inspired by the Forward-Backward algorithm [24] and the Inside-Outside algorithm [1, 16, 19]. The Center-Surround algorithm is based on recursive calculations involving center and surround variables which we presently define.

For any vertex \( \delta \) of any admissible tree \( T \), let \( T_\delta \) be the subtree of \( T \) rooted at \( \delta \), and let \( T_\delta^* \) be the portion of \( T \) that is obtained by removing all descendants of \( \delta \) (however, \( \delta \) itself is a part of \( T_\delta^* \)). If \( T \in \Omega_u, x_\delta = j, \) and \( \mathcal{Y}(\delta) = \Box_{pq} \), then we let \( c_{pq}^j(u, T, \delta) \) be the product of probabilities of all the production rules involved in constructing \( T_\delta \); otherwise, \( c_{pq}^j(u, T, \delta) = 0 \):

\[
\begin{align*}
  c_{pq}^j(u, T, \delta) &\triangleq \begin{cases} 
    \prod_{\alpha \in \mathcal{V}_{\delta, \text{int}}} P_{\text{prod}}(A_\alpha), & \text{if } \mathcal{Y}(\delta) = \Box_{pq} \text{ and } x_\delta = j, \\
    0 & \text{otherwise,}
  \end{cases} \\
\end{align*}
\]

(13)

where \( \mathcal{V}_{\delta, \text{int}} \) is the set of all internal vertices of \( T_\delta \). For a fixed \( T_\delta \), we define the **center variable** \( c_{pq}^j(u) \) as follows:

\[
\begin{align*}
  c_{pq}^j(u) &\triangleq \sum_{T : T \in \Omega_u \text{ and } T_\delta \text{ is fixed}} c_{pq}^j(u, T, \delta).
\end{align*}
\]

(14)

\(^4\)Note that our definition of maximum likelihood estimation is distinct from the maximization of \( P'(u^1, \ldots, u^I|G) \) defined in Eq. (12).
In other words, we keep $T_\delta$ fixed and sum over all possible subtrees $T_\delta$ with root state $x_\delta = j$. Note that $c^j_{pq}(u)$ is in fact the same for any $T_\delta$ with $x_\delta = j$ because every term $c^j_{pq}(u, T, \delta)$ in the summation only depends on $T_\delta$.

It follows from these definitions (13,14) as well as from Eq. (5) and Lemma 2, that $c^j_{\lambda,M}(u, T, \rho)$ is simply the conditional probability of $T$ given that its root state is $j$:

$$c^j_{\lambda,M}(u, T, \rho) = P(T|\Omega^j), \quad \forall T \in \Omega_u,$$

where $\Omega^j$ is the set of all trees whose root state is $j$. Summing over all $T \in \Omega_u$, we obtain an expression for the conditional probability of the image $u$ in terms of a center variable:

$$c^j_{\lambda,M}(u) = P(u|\Omega^j). \quad (15)$$

It is easily seen that all other center variables are also conditional probabilities of events in $\Omega$.

If $T \in \Omega_u$, $x_\delta = j$, and $\mathcal{Y}(\delta) = \Box_{pq}$, then we let $s^j_{pq}(u, T, \delta)$ be the product of the probability of the root state of $T$ and the probabilities of all the production rules which are not involved in constructing $T_\delta$; otherwise, $s^j_{pq}(u, T, \delta) = 0$:

$$s^j_{pq}(u, T, \delta) = \begin{cases} 
    P_{\text{root}}(x_\rho) \prod_{\alpha \in \mathcal{V}_{\delta,\text{int}}} P_{\text{prod}}(A_\alpha) & \text{if } \mathcal{Y}(\delta) = \Box_{pq} \text{ and } x_\delta = j, \\
    0 & \text{otherwise},
\end{cases} \quad (16)$$

where $\mathcal{V}_{\delta,\text{int}}$ is the set of all internal vertices of $T$ that do not belong to $T_\delta$. For a fixed $T_\delta$, we define the **surround variable** $s^j_{pq}(u)$ as follows:

$$s^j_{pq}(u) \Delta \sum_{T : T \in \Omega_u \text{ and } T_\delta \text{ is fixed}} s^j_{pq}(u, T, \delta). \quad (17)$$

An important consequence of Eqs. (13) and (16) is that, for any tree $T \in \Omega_u$ having a vertex $\delta$ with state $j$ which dominates $\Box_{pq}$,

$$P(T) = s^j_{pq}(u, T, \delta)c^j_{pq}(u, T, \delta).$$

We just mention here without proof that it is also possible to interpret all the surround variables as probabilities of events in $\Omega$.

Now that we have defined the center and surround variables, we proceed to describe our three inference algorithms in the next three subsections. Recall that our notation for SRTs, deterministic trees, and images is summarized in Table II in Appendix.
A. Likelihood Computation

1) Recursive Computation of the Center Variables: Eq. (15) tells us that, given a fixed PCFG, the probability of the image $u$ can be easily computed if the center variables $c_{j,1,M}^j(u)$ are known for all possible root states $j \in \mathcal{N}$:

$$P(u) = \sum_{j \in \mathcal{N}} P(u|\Omega^j)P(\Omega^j) = \sum_{j \in \mathcal{N}} c_{j,1,M}^j(u)P_{\text{root}}(j).$$  \(18\)

Our definition of the center variables suggests that it should be possible to express $c_{j,1,M}^j(u)$ in terms of center variables defined on rectangular subdomains of $\square_{1,M}$. The following proposition, illustrated in Fig. 6, shows that this is indeed the case: $c_{j,1,M}^j(u)$ can be computed recursively. The first term of the recursion formula (19) corresponds to summing over all possible horizontal splittings (Fig. 6(a)) and the second term corresponds to the vertical splittings (Fig. 6(b)).

**Proposition 3.** For any nonempty rectangular domain $\square_{pq} \subset \square_{1,M}$ with $p \neq q$, and any $j \in \mathcal{N}$,

$$c_{pq}^j(u) = \sum_{d=p_1}^{q_1-1} \sum_{k \in \mathcal{N}} \sum_{\ell \in \mathcal{N}} P_{\text{prod}}(j \rightarrow k, \ell)c_{p_1+q_2}^{\ell}(u)c_{(d+1,p_2)}^{k}(u)$$

$$+ \sum_{d=p_2}^{q_2-1} \sum_{k \in \mathcal{N}} \sum_{\ell \in \mathcal{N}} P_{\text{prod}}(j \rightarrow k, \ell)c_{p_2+q_1}^{\ell}(u)c_{(p_1+1,d)}^{k}(u),$$  \(19\)

where our convention is that any sum over an empty set is zero. For any $p \in \square_{1,M}$ and any $j \in \mathcal{N}$,

$$c_{pp}^j(u) = P_{\text{prod}}(j \rightarrow u).$$  \(20\)

**Proof.** See Appendix.
Combining Proposition 3 with Eq. (18) gives a recursive algorithm for calculating the probability $P(u)$ of an image $u$. This algorithm computes the center variables for each nonempty subrectangle $\Box_{pq}$ (with $p \neq q$) of the rectangle $\Box_{1,M}$. A simple calculation shows that the total number of such subrectangles is $M_1 M_2 (M_1 + 1)(M_2 + 1)/4 = O(M_1^2 M_2^2)$. For each such subrectangle, each nonterminal production rule contributes $O(M_1 + M_2)$ computations via the sums in Eq. (19). Since there are altogether $2|\mathcal{N}|^3$ nonterminal production rules, where $|\mathcal{N}|$ is the number of nonterminal states, the overall time complexity is $O(M_1^2 M_2^2 (M_1 + M_2)|\mathcal{N}|^3)$.

It has been our experience, however, that useful probabilistic grammars typically have many nonterminal production rules with zero probabilities. For the simple examples considered in Section V, the number of nonterminal rules with nonzero probabilities is $O(|\mathcal{N}|)$, as illustrated in Table I. This can be exploited\(^5\) to reduce the time complexity of the algorithm to $O(M_1^2 M_2^2 (M_1 + M_2)|\mathcal{N}|)$. We are currently investigating methods for further reducing the running time by restricting the set of possible trees, e.g., using methods discussed in Section VI.

We now consider the space complexity of our recursive algorithm—i.e., the amount of memory it requires. During the computation of the center variables $c_{i,M}^j(u)$ via a recursive call to Eq. (19), we need to simultaneously store $c_{p,q}^j(u)$ for each subrectangle $\Box_{p,q}$ of $\Box_{1,M}$, and for each $j \in \mathcal{N}$. Therefore, the space complexity is $O(M_1^2 M_2^2 |\mathcal{N}|)$. The sparseness of the probabilistic grammar (i.e. the fact that many production rules have zero probability) can in some cases cause many center variables to be zero. In this case, the overall memory complexity can be drastically reduced by using memory-efficient techniques such as hash tables. Restricting the set of possible trees may lead to further reductions in memory complexity.

We note that recursion (19) is easily modified for the case of $D$-dimensional data: the two triple summations are replaced with $D$ triple summations, one for each split orientation. The time complexity is then $O(M_1^2 \cdots M_D^2(M_1 + \cdots + M_D)D|\mathcal{N}|^3)$ which is $O(|\Box_{1,M}|^{2+\frac{1}{D}}D|\mathcal{N}|^3)$ for signal domains which are $D$-dimensional hypercubes, where we denote the total number of samples in the multidimensional signal by $|\Box_{1,M}|$. The space complexity is still $O(|\Box_{1,M}|^2|\mathcal{N}|)$.

We conclude our discussion of complexity by commenting on the non-asymptotic case when $D$ is small. This case is of particular interest since it corresponds to a variety of data such as 1-D signals ($D = 1$), planar images ($D = 2$), volumetric images and video ($D = 3$). Observe that increasing the dimensionality of the problem will, for an appropriately large $M$, reduce the time complexity in this case.

\(^5\)By not performing any calculations involving zero-probability rules.
This is quite atypical for algorithms that handle multidimensional data.

2) Recursive Computation of the Surround Variables: The likelihood can also be computed from the surround variables. The surround recursion uses the center variables which therefore must be precomputed. The surround recursion (22) is illustrated in Fig. 7. The four terms in Eq. (22) correspond to two different cases for a horizontal split of the parent rectangle and two cases for a vertical split.

**Proposition 4.** For any $p \in \square_{1,M}$,

$$P(u) = \sum_{j \in \mathcal{N}} s_{pp}^j(u)c_{pp}^j(u).$$

For any nonempty rectangular domain $\square_{pq} \subset \square_{1,M}$ with $p \neq q$, and any $j \in \mathcal{N}$,

$$s_{pq}^j(u) = \sum_{e=1}^{p_1-1} \sum_{k \in \mathcal{N}} \sum_{\ell \in \mathcal{N}} s_{(e,p_2),q}^{k}(u)P_{\text{prod}}(k \rightarrow \ell, j)c_{(e,p_2),(p_1-1,q_2)}^{\ell}(u)
+ \sum_{e=q_1+1}^{M_1} \sum_{k \in \mathcal{N}} \sum_{\ell \in \mathcal{N}} s_{p,(e,q_2)}^{k}(u)P_{\text{prod}}(k \rightarrow j, \ell)c_{(q_1+1,p_2),(e,q_2)}^{\ell}(u)$$
\[ + \sum_{e=1}^{p_2-1} \sum_{k \in N} \sum_{\ell \in N} s_{(p_1,e),q}^k (u) P_{\text{prod}}(k \rightarrow \ell, j) c_{(p_1,e), (q_1,p_2-1)}^\ell (u) \]
\[ + \sum_{e=q_2+1}^{M_2} \sum_{k \in N} \sum_{\ell \in N} s_{p,(q_1,e)}^k (u) P_{\text{prod}}(k \rightarrow j, \ell) c_{(p_1,q_2+1), (q_1,e)}^\ell (u), \]

where our convention is that any sum over an empty set is zero. The base case for this recursion is:

\[ s_{1,M}^j(u) = P_{\text{root}}(j). \]

**Proof** is similar to the proof of Proposition 3 which is given in the Appendix.

The computational complexity of the surround recursions is similar to that of the center recursions. The latter was discussed above.

**B. MAP Tree Estimation**

In this section, we present an algorithm for extracting the most probable tree \( \hat{T} \) from \( \Omega_u \), for a given image \( u \). The probability of the most probable tree in \( \Omega_u \) with root state \( j \) is denoted \( g_j(u) \). The recursive formulas are a simple variant of the center recursion of the previous subsection (see Proposition 3 and Fig. 6), with “\( \sum \)” replaced by “\( \max \)”. We therefore state them without proof. The base case is:

\[ g_j^p(u) = P_{\text{prod}}(j \rightarrow u). \]

We recursively calculate \( g_{pq}^j(u) \) for any rectangle in terms of probabilities associated with smaller rectangles:

\[ g_{pq}^{jh}(u) = \max_{d \in \{p_1, \ldots, q_1-1\}, \ell \in N} P_{\text{prod}}(j \rightarrow h, k) g_{p,(d,q_2)}^k (u) g_{(d+1,p_2),q}^\ell (u), \]
\[ g_{pq}^{ju}(u) = \max_{d \in \{p_2, \ldots, q_2-1\}, \ell \in N} P_{\text{prod}}(j \rightarrow u, k) g_{p,(q_1,d)}^k (u) g_{(p_1,d+1),q}^\ell (u), \]
\[ g_{pq}^j(u) = \max(g_{pq}^{ju}(u), g_{pq}^{jh}(u)). \]

We in addition store the four-tuple of parameters \((o, k, l, d)\) which have led to the maximal \( g_{pq}^j \) where \( o \in \{h, v\} \) stands for the split orientation. We call this four-tuple \( f_{pq}^j(u) \). If \( g_{pq}^{jh}(u) > g_{pq}^{ju}(u) \), then

\[ f_{pq}^j(u) = (h, \arg \max_{(k,l,d)} P_{\text{prod}}(j \rightarrow h, k) g_{p,(d,q_2)}^k (u) g_{(d+1,p_2),q}^\ell (u)), \]

Otherwise,

\[ f_{pq}^j(u) = (v, \arg \max_{(k,l,d)} P_{\text{prod}}(j \rightarrow u, k) g_{p,(q_1,d)}^k (u) g_{(p_1,d+1),q}^\ell (u)). \]
If the maximum is not unique, we can choose an arbitrary maximizing four-tuple. The probability of the MAP tree $\hat{T}$ is calculated from the $g$ variables,

$$P(\hat{T}) = \max_{j \in N} g^j_{1,M}(u)P_{\text{root}}(j),$$

and the MAP tree itself is constructed from the list of the $f$ variables.

Our discussion above of the computational complexity of the center recursions also applies here, as well as the various possibilities for reducing the computational complexity.

C. Parameter Estimation

Given a set $U = \{u^1, \ldots, u^I\}$ of $I$ independent observations, we use the expectation maximization (EM) algorithm [3] to estimate the model parameters. In this section, we denote the likelihood by $P(U|G)$, explicitly indicating its dependence on the PCFG $G$. Starting with any initial PCFG $G^0$, the EM algorithm generates a sequence of PCFGs $G^0, G^1, G^2, \ldots$ which is guaranteed to climb the likelihood surface and therefore allows one to improve the PCFG parameters, starting with any initial parameter values. This result is based on the following simple proposition which we adapt from [3].

**Proposition 5.** Let

$$Q(G^{n+1}, G^n) = \Delta \sum_{i=1}^I \sum_{T \in \Omega_{u^i}} P(T|u^i, G^n) \log P(T|G^{n+1}).$$

(24)

If $Q(G^{n+1}, G^n) > Q(G^n, G^n)$ then $P(U|G^{n+1}) > P(U|G^n)$.

**Proof.** This proof is adapted from [3]. We use the independence of the individual observations $u^i$:

$$\log \frac{P(U|G^{n+1})}{P(U|G^n)} = \sum_{i=1}^I \log \frac{P(u^i|G^{n+1})}{P(u^i|G^n)} = \sum_{i=1}^I \log \frac{\sum_{T \in \Omega_{u^i}} P(T|G^{n+1})}{\sum_{T \in \Omega_{u^i}} P(T|G^n)}$$

$$= \sum_{i=1}^I \log \sum_{T \in \Omega_{u^i}} \left( \frac{P(T|G^n)}{P(u^i|G^n)} \cdot \frac{P(T|G^{n+1})}{P(T|G^n)} \right)$$

$$= \sum_{i=1}^I \log \sum_{T \in \Omega_{u^i}} \left( P(T|u^i, G^n) \cdot \frac{P(T|G^{n+1})}{P(T|G^n)} \right)$$

$$\geq \sum_{i=1}^I \sum_{T \in \Omega_{u^i}} \left( P(T|u^i, G^n) \cdot \log \frac{P(T|G^{n+1})}{P(T|G^n)} \right) = Q(G^{n+1}, G^n) - Q(G^n, G^n) > 0,$$

where we used the fact that $\log$ is a concave function and applied Jensen’s inequality.

This proposition suggests that we can improve our estimate $G^n$ by choosing a PCFG $G^{n+1}$ which makes the $Q$ function larger. Specifically, the EM algorithm chooses $G^{n+1}$ so as to maximize $Q(G, G^n)$. January 30, 2003 DRAFT
over all possible probability assignments \(P_{\text{root}}, P_{\text{prod}}\) of the PCFG \(G = (\mathcal{N}, \mathcal{T}, \mathcal{P}, P_{\text{root}}, P_{\text{prod}})\):

\[
G^{n+1} = \arg \max_{P_{\text{root}}, P_{\text{prod}}} Q(G, G^n), \quad \text{where } G = (\mathcal{N}, \mathcal{T}, \mathcal{P}, P_{\text{root}}, P_{\text{prod}}).
\] (25)

We note that no optimization is performed over the sets \(\mathcal{N}, \mathcal{T}, \mathcal{P}\); however, this does not mean that these sets are always kept fixed by the EM algorithm. Some production rules which are in \(\mathcal{P}\) may, in effect, be eliminated by the algorithm because their probability may evolve to zero. If these production rules happened to be terminal, it may also happen that the corresponding member of \(\mathcal{T}\) is eliminated, i.e., that it is no longer part of any rule whose probability is nonzero. However, no new production rules can be created, and, because of the normalization equations, nonterminal states cannot be eliminated.

We now derive the update equations for the PCFG parameters.

**Proposition 6.** Suppose we have \(I\) independent observations \(u^1, \ldots, u^I\). Let \(y^{i,n}\) be the inverse likelihood of the \(i\)-th observation after the \(n\)-th iteration of the EM algorithm:

\[
y^{i,n} = \frac{1}{P(u^i|G^n)} = \left( \sum_{j \in \mathcal{N}} c^j_{1,M^i}(u^i)P_{\text{root}}^n(j) \right)^{-1},
\]

where \(M^i = (M_1^i, M_2^i)\) is the size of the image \(u^i\). Then the update equations for the PCFG parameters corresponding to Eq. (25) are:

\[
P_{\text{root}}^{n+1}(j) = \frac{1}{I} \sum_{i=1}^{I} y^{i,n}c^j_{1,M^i}(u^i)P_{\text{root}}^n(j),
\] (26)

\[
P_{\text{prod}}^{n+1}(j \rightarrow h, k, \ell) = \frac{\sum_{i=1}^{I} y^{i,n} \sum_{p,q} s^j_{pq}(u^i)P_{\text{prod}}^n(j \rightarrow h, k, \ell) \sum_{d=p_1}^{q_1-1} c^k_{p,(d,q_2)}(u^i)c^\ell_{(d+1,p_2),q}(u^i) \sum_{d=p_2}^{q_2-1} c^k_{p_1,(d+1,1),d}(u^i)c^\ell_{(p_1,d+1),q}(u^i)}{\sum_{i=1}^{I} y^{i,n} \sum_{p,q} s^j_{pq}(u^i)c^j_{pq}(u^i)},
\] (27)

\[
P_{\text{prod}}^{n+1}(j \rightarrow v, k, \ell) = \frac{\sum_{i=1}^{I} y^{i,n} \sum_{p,q} s^j_{pq}(u^i)P_{\text{prod}}^n(j \rightarrow v, k, \ell) \sum_{d=p_1}^{q_1-1} c^k_{p,(1,d+1,q_2)}(u^i)c^\ell_{(q_1,d),q}(u^i)}{\sum_{i=1}^{I} y^{i,n} \sum_{p,q} s^j_{pq}(u^i)c^j_{pq}(u^i)},
\] (28)

\[
P_{\text{prod}}^{n+1}(j \rightarrow u) = \frac{\sum_{i=1}^{I} y^{i,n}P_{\text{prod}}^n(j \rightarrow u) \sum_{p:w_p=u} s^j_{pq}(u^i)}{\sum_{i=1}^{I} y^{i,n} \sum_{p,q} s^j_{pq}(u^i)c^j_{pq}(u^i)},
\] (29)

where all center and surround variables in the righthand sides are calculated using the PCFG \(G^n\), and where each double summation over \(p\) and \(q\) is done over all such pairs \((p, q)\) that \(\Box_{p,q}\) is a nonempty rectangular subdomain of \(\Box_{1,M^i}\). As before, our convention is that any sum over an empty set is zero.
The rate of correct classification of noisy digit images, as a function of the noise level $\varepsilon$.

**Proof.** See Appendix.

The space complexity of the EM algorithm is the same as that of the center and surround recursions. The time complexity, however, depends not only on the time complexity of the center and surround recursions but also on the number of iterations which is not predictable. The running time of the parameter estimation algorithm, however, is not as critical as for the MAP and likelihood calculation algorithms, since for any specific problem the model parameters are estimated only once, off-line.

V. EXPERIMENTAL ILLUSTRATIONS OF THE ALGORITHM

In this section, we illustrate the potential value of our methods with simple examples.

A. Experiment 1: Classification of Noisy Images

We apply our likelihood computation algorithm of Section IV-A to classifying binary images of noisy digits. Our data set consists of the ten digits from the X WINDOWS 9x15 font whose characters are 10x7 pixel images, placed at various locations on a white 14 x 11 background. These images are corrupted by synthetic noise which independently flips every pixel with probability $\varepsilon$.

For each noise-free digit $k = 0, 1, \ldots, 9$, a probabilistic grammar $G_k$ is obtained from the EM algorithm of Section IV-C, by training on a single 10x7 image of the digit. Each grammar $G_k$ is then manually expanded (i.e., several new nonterminal states and nonterminal production rules are introduced) to obtain a new probabilistic grammar capable of placing the image of the digit $k$ at any location on a white background. Using these PCFGs, a PCFG $G_{k,\varepsilon}$ is obtained for each level of noise $\varepsilon$ and each digit $k = 0, 1, \ldots, 9$, by manually modifying the terminal production rule probabilities to model the noise. For example, the PCFG for the digit zero with noise level $\varepsilon = 0.05$ is given in Table I (the production rule probabilities given here are approximate, with only two significant digits).
TABLE I

PCFG $G_{0.0.05}$ FOR THE DIGIT ZERO WITH NOISE LEVEL $\varepsilon = 0.05$.

</table>

We now describe the results of our classification experiments with noisy digit images: 900 experiments for each noise level $\varepsilon = 0, 0.01, 0.02, 0.03, 0.04, 0.05, 0.1, 0.2$. Specifically, for each digit we consider nine different shifts: centered on the $14 \times 11$ background; shifted to the left, right, top, bottom, upper left corner, upper right corner, lower left corner, and lower right corner. For each shift of each digit, we generate 10 noisy versions with independent noise realizations for each noise level $\varepsilon$. Each of the 900 images is classified by calculating its likelihoods with respect to the ten PCFGs $G_{0,\varepsilon}, \ldots, G_{9,\varepsilon}$ and choosing the hypothesis corresponding to the largest likelihood. Implemented in C, each likelihood calculation takes about 0.3 seconds on an 800 MHz Pentium III processor—i.e., classifying each image takes about 3 seconds. The PCFGs obtained in this experiment are very sparse. For example, even though PCFG $G_{0,0.05}$ (see Table I) has 30 nonterminal states, only 60 nonterminal production rules have nonzero
Our experiments are summarized in Fig. 8, which shows a plot of our estimates of the correct classification probability as a function of the noise level \( \varepsilon \), from the noise-free case \( \varepsilon = 0 \) to the extremely noisy case of \( \varepsilon = 0.2 \). This latter case corresponds to an average of about 31 incorrect pixels per \( 14 \times 11 \) image,
which, as shown in Fig. 9, makes some images unrecognizable to a human. Our estimate of the correct classification probability is simply the number of correct classifications among our 900 experiments, divided by 900. Assuming that the actual correct classification probability is \( P_\varepsilon \), and that our experiments are independent, the standard deviation of our estimate is \( \sqrt{(P_\varepsilon - P_\varepsilon^2)/900} \leq \sqrt{(1/4)/900} = 1/60 \) which is sufficiently accurate for this illustrative example. The plot in Fig. 8 demonstrates the excellent performance of our algorithm and graceful degradation for very noisy images.

Several images from our experiments are shown in Fig. 9. The three rows correspond to noise levels \( \varepsilon = 0.05, 0.1, \) and \( 0.2 \), respectively. With \( \varepsilon = 0.05 \), a few of the images are difficult for a human to recognize; most of the ones with \( \varepsilon = 0.2 \) are unrecognizable.

Emphasizing that it is not the goal of this paper to compete with state-of-the-art character recognition algorithms (in fact, a simple algorithm, such as a matched filter, would probably perform very well in the simple example we have just described), we note nevertheless that the performance of our algorithm in this example is promising and demonstrates its viability and potential.

**B. Experiment 2: Segmentation and Recognition**

In this example, we use the MAP estimation algorithm of Section IV-B to extract a string of digits from a noisy image and classify these digits.

The PCFGs for all ten digits from Experiment 1 are embedded in a larger PCFG which describes
strings of seven digits on a white background. Just as in Experiment 1, the PCFG is modified to account for noise. In this PCFG, there are ten special nonterminal states digit-0, digit-1, \ldots, digit-9 which are used to label the ten digits. For example, \( x_\alpha = \text{digit-0} \) is interpreted to mean that digit zero is present in the image and is situated in \( \mathcal{Y}(\alpha) \).

Given an image such as that of Fig. 10(a), we use our algorithm to estimate the MAP tree. For each internal vertex \( \alpha \) of this tree such that \( x_\alpha = \text{digit-}k \), we extract the rectangle \( \mathcal{Y}(\alpha) \) and label it as digit \( k \). Our algorithm therefore produces the segmentation of our image into digits and background, and recognizes each digit. For the input image of Fig. 10(a), this results in Fig. 10(b).

VI. DISCUSSION AND CONCLUSIONS

A. The Inside-Outside Algorithm

As indicated above, the Center-Surround algorithm was motivated by the Inside-Outside algorithm [1, 16, 19] for the 1-D PCFG defined by Eqs. (1,2). In fact, when the number of dimensions \( D \) is equal to one, the multidimensional grammar of Eqs. (7,8) reduces to the 1-D grammar of Eqs. (1,2), and the Center-Surround algorithm reduces to the Inside-Outside algorithm. This is also equivalent to the 2-D case of the Center-Surround algorithm for images whose height or width is one. Indeed, it is easily verified that, for \( M_1 = 1 \), the center recursion (19) becomes the inside recursion (Eq. (6) in [16]), the surround recursion (22) becomes the outside recursion (Eq. (8) in [16]), and the MAP estimation formulas become identical to Eqs. (20) and (21) in [16]. As we have shown in Section III, however, the leap from the 1-D framework to multiple dimensions is not a simple one: the issue arises of unambiguously associating a multidimensional signal with every tree. This issue does not arise in 1-D. Our framework handles this issue by insuring that at most one signal can correspond to a tree. This is proven in the Admissibility Theorem of Section III. On the other hand, in multiple dimensions, there exist trees which do not correspond to a signal and which we call inadmissible trees. This property is immaterial to the algorithms that comprise the Center-Surround algorithm. The existence of inadmissible trees, however, makes the problem of sampling from our model (i.e., producing a sample path which is admissible) much more difficult than sampling from the 1-D PCFG of Eqs. (1,2). This problem is open and is one of the avenues of our current research.

B. Fixed-Tree Discrete-State Multiscale Models

Another inspiration for our work is research on multiscale statistical modeling of images with quadtrees of fixed structure [5, 6, 18]–i.e., quadtrees such as the one in Fig. 11(a) for which the set of vertices and
Fig. 11. (a) A quadtree for a $4 \times 4$ image. (b) An $\Omega$-tree generated by our image PCFG. This particular $\Omega$-tree is equivalent to the quadtree depicted in (c) which is obtained by combining the three encircled vertices of the $\Omega$-tree into one.

edges is fixed and does not depend on the image. A fixed quadtree is thus able to model a $2^n \times 2^n$ image where $n$ is determined by the depth of the tree. It can be seen that a quadtree structure can be achieved in our 2-D PCFG of Eqs. (7,8) by restricting it in such a way that, in each $\Omega$-tree, horizontal and vertical productions are forced to alternate. It is easy to show that these restrictions can be made by setting the probabilities of certain production rules in Eqs. (7,8) to zero. This is illustrated with a particular tree in Fig. 11(b) which models a $2 \times 2$ image. To make this model identical to that of [5, 6], each triple of vertices $(\alpha, C_1(\alpha), C_2(\alpha))$ such that $\alpha$ belongs to an even-numbered generation on the tree, is replaced by a single vertex with vector state $(x_\alpha, x_{C_1(\alpha)}, x_{C_2(\alpha)})$. For example, the three upper vertices of the $\Omega$-tree in Fig. 11(b) become a single vertex with aggregate state $(0,1,3)$, to result in the quadtree of Fig. 11(c).

Our framework is more flexible than that of [5, 6]: instead of imposing a quadtree structure on an image, it can adapt the structure of the tree to the data. For this flexibility, we pay a computational cost. The time complexity of likelihood calculation and MAP estimation in [5, 6] is $O(M_1M_2|N|^2)$ for an $M_1 \times M_2$ image and for a model whose set of hidden states has size $|N|$. As we saw in Section IV, the corresponding complexity in our case could be much higher. Our current research agenda includes exploiting the sparsity of PCFGs to reduce computational complexity, as well as developing approximate algorithms with improved speed and memory performance.

C. Continuous-State Multiscale Models

Using quadtrees of fixed structure to develop statistical multiscale models for images has its origins in [2, 7, 18] where a continuous-state model was introduced, and the resulting scale-recursive algorithms were devised for calculating the linear least-squares estimates. We are currently pursuing the extension of our framework to the continuous-state case. In this case, discrete probability distributions $P_{\text{root}}$ and $P_{\text{prod}}$ are replaced with probability densities.
In addition to having a theoretical interest, it is suggested by previous work, such as [17], that this research topic may have significant practical implications. For example, [17] supplemented the traditional hidden Markov models with continuous random variables which model the durations of phonetic segments. These random variables were specified by a parametric family of probability density functions which were given by a small number of parameters. This greatly reduced the complexity of the model.

The Center-Surround algorithm was developed above using the most typical measurement scenario, namely, that every pixel value of an image or a set of images is observed. The algorithm is easily generalized to several cases where there may be some additional coarse-scale information, and where some pixel values may be unknown. We now list in detail these alternative scenarios that can be handled by our algorithm.

- It may be known a priori—for example, from a preprocessing segmentation step—that certain groups of pixels belong together. In this case, any tree which does not respect these groupings must have zero probability. For example, preprocessing may indicate that the image of Fig. 12(a) can only be split horizontally along the thick line in Fig. 12(b) but not anywhere else. We use $D_{pq,h}$ to denote the list of all allowed horizontal split locations for an image subdomain $\Box_{pq}$. More formally, $D_{pq,h}$ is the set of all numbers $d$ such that $\mathcal{Y}^{-1}(\Box_{p,(d,q2)})$ and $\mathcal{Y}^{-1}(\Box_{(d+1,p2),q})$ are allowed to be the children of $\mathcal{Y}^{-1}(\Box_{pq})$. $D_{pq,h}$ can be any (possibly empty) subset of $\{p_1, \ldots, q_1-1\}$, see Fig. 6(a). For example, $D_{(1,1),(6,6),h} = \{4\}$ for Fig. 12(b).

Similarly, $D_{pq,v}$ is the list of all allowed vertical split locations for $\Box_{pq}$, i.e., the set of all numbers $d$ such that $\mathcal{Y}^{-1}(\Box_{p,(q1,d)})$ and $\mathcal{Y}^{-1}(\Box_{(p1,d+1),q})$ are allowed to be the children of $\mathcal{Y}^{-1}(\Box_{pq})$. $D_{pq,v}$ can be any (possibly empty) subset of $\{p_2, \ldots, q_2-1\}$, see Fig. 6(b). In the example of Fig. 12(c), $D_{(1,1),(6,6),v} = \{2,3\}$.

- Some information may be available about the states of internal vertices. For example, we may know a priori the state of the ancestor $\alpha$ of a certain region $\Box_{pq}$. More generally, we use $N_{pq}$ to denote the list of all possible states for the internal vertex $\alpha$ whose yield is $\Box_{pq}$ if such vertex exists. $N_{pq}$ can be any nonempty subset of $\mathcal{N}$.

- Some information about the image pixels, on the other hand, may be missing: for example, the values for a certain group of pixels may be unobserved. More generally, we use $T_p$ to denote the list of all possible states for the leaf $\Box_p$. $T_p$ can be any nonempty subset of $\mathcal{T}$, in particular, it may...
Fig. 12. (a) A 6 × 6 grayscale image. (b) A single allowed horizontal split location for the 6 × 6 image domain, obtained through a preprocessing segmentation step. (c) Two allowed vertical split locations.

consist of a single pixel value.

We assume that the dimensions $M = (M_1, M_2)$ of the observed image are part of the observations. Our observation information in this more general case consists of $M$ and the constraint sets $D_{pq,h}, D_{pq,v}, N_{pq}$, and $T_p$. In other words, we define our observation information $v$ as follows:

$$v = \{M\} \cup \{N_{pq}, D_{pq,h}, D_{pq,v}\}_{p,q;\square_{pq} \subseteq \square_{1,M}} \cup \{T_p\}_{p \in \square_{1,M}}.$$ (30)

We then define $\Omega_v$ to be the set of all admissible $\Omega$-trees that satisfy the constraints $v$, and we use $P(v)$ as a shorthand notation for $P(\Omega_v)$.

The generalizations of the center and surround recursions, the MAP recursions, and the EM update formulas for this case, are straightforward. We just give the center recursion formulas for data $v$ as an illustration. For any nonempty rectangular domain $\square_{pq} \subset \square_{1,M}$ with $p \neq q$, and any $j \in N_{pq}$, Eq. (19) is modified as follows:

$$c_{pq}(v) = \sum_{d \in D_{pq,h}} \sum_{k \in N_{p,(d,q_2)}} \sum_{\ell \in N_{(d+1,p_2),q}} P_{prod}(j \overset{h}{\rightarrow} k, \ell)c_{p,(d,q_2)}^h(v)c_{(d+1,p_2),q}^\ell(v)$$
$$+ \sum_{d \in D_{pq,v}} \sum_{k \in N_{p,(q_1,d)}} \sum_{\ell \in N_{(p_1,d+1),q}} P_{prod}(j \overset{v}{\rightarrow} k, \ell)c_{p,(q_1,d)}^h(v)c_{(p_1,d+1),q}^\ell(v),$$ (31)

where our convention is that any sum over an empty set is zero. For any $p \in \square_{1,M}$ and any $j \in N_{pp}$, the initialization equation is:

$$c_{pp}(v) = \sum_{u \in T_p} P_{prod}(j \rightarrow u).$$ (32)

The probability of data $v$ is computed from the center variables $c_{1,M}^j(v)$:

$$P(v) = \sum_{j \in N_{1,M}} c_{1,M}^j(v)P_{root}(j).$$ (33)
The advantage of this more general formulation is that it allows one to handle a wide variety of different modes of observation. In particular, the “partially bracketed” scenario of [22] can be handled by our formulation. This can dramatically reduce the time and space complexity of the likelihood calculation and MAP estimation algorithms. As shown by [22] in the context of natural language processing and by our own preliminary experiments in the context of image classification, partial bracketing and its generalizations also lead to significant improvements in parameter estimation algorithms, both improving the quality of estimates and reducing the computational cost.

We finally remark that the case of $D$ dimensions is handled by having $D$ different constraint sets $D_{pq,o}$, one for each split orientation $o$.

E. Further Generalizations of Our Model

Our definition of SRTs requires each leaf of an admissible tree to correspond to a single image pixel. As a consequence, the recursive algorithms for likelihood calculation and MAP estimation always must go down to the pixel level, even if there is no observation associated with some pixels. In certain cases, there may be aggregate information about a rectangular group of pixels. In these cases, there can be substantial computational advantages to modeling this aggregated rectangle by a single leaf vertex. We are now investigating several possible ways of generalizing SRTs to such a scenario.

The current formulation of the SRT model is, moreover, based on the use of a rectangular lattice. This is a restriction for applications in which the observations are on an arbitrary graph. For example, in some applications images may be initially segmented into regions with arbitrary shapes. Information extracted from such regions is then best represented using a sparsely connected graph structure with each vertex corresponding to a segmented region of the image and each edge connecting a pair of neighboring regions. We are currently developing methods for adapting the Center-Surround algorithm to such arbitrary graph structures so that it can be better used in applications such as image interpretation and classification.

F. Applications

Multiscale models are important both because they naturally describe many aspects of the world and also because of computational advantages (many problems can be solved more efficiently by organizing computations in a multiscale manner). This has motivated a large body of research on multiresolution representations, linear and nonlinear scale-spaces, and multiscale statistical models.

Our multiscale model is unique in that it is both statistical and adaptive (i.e., able to adjust the tree structure). We therefore anticipate that SRTs and the Center-Surround algorithm will be useful in a wide
variety of applications where it is important to extract an optimal hierarchical structure of the data.

VII. ACKNOWLEDGMENTS

We would like to thank Yan Huang, Bill Nagel, James Sherman, and Eric Théa for developing implementation of the Center-Surround algorithm and running the experiments of Section V, as well as for stimulating and helpful discussions.

PROOF OF LEMMA 1

We prove this lemma for $i' = i + 1$; the case of any other $i'$ follows by induction. Since $T \in \Pi_i$, note that the set $[T]_{i+1}$ is obtained by applying all possible production rules at all the leaves of $T$ with
nonterminal states. Let \( \{\alpha_1, \ldots, \alpha_p\} \) be the set of all the leaves of \( T \) with nonterminal states, and let \( j_1, \ldots, j_p \) be the corresponding states. We only prove the lemma for \( p = 1 \); the case \( p > 1 \) is similar. When \( p = 1 \),

\[
P_{i+1}([T]_{i+1}) = \sum_{\Lambda \in \mathcal{P}^j} P_i(T) P_{prod}(\Lambda) \equiv P_i(T). \quad \blacksquare
\]

**Proof of Lemma 2**

The set \( \Omega^j_0 = \Pi_0^j \) consists of a single 0-pruned tree of depth zero whose root state is \( j \). This tree is, in other words, a single vertex with state \( j \) which has no children. Let us call this tree \( T \). According to our definition (5), \( P_0(T) = P_{root}(j) \). Now suppose \( i > 0 \). Note that \( [T]_i \) is the set \( \Omega^j_i \) since \( \Omega^j_i \) is the set of all trees in \( \Omega_i \) whose 0-pruning results in \( T \). Therefore, Lemma 1 can be applied to yield: \( P_0(T) = P_1([T]_i) = P_1(\Omega^j_i) \) which, combined with \( P_0(T) = P_{root}(j) \), implies the statement of Lemma 2. \( \blacksquare \)

**Proof of Lemma 3**

(i) *Proof of the fact that \( \mathcal{A}_\infty \) is an algebra*

For any subset \( A \) of \( \Omega_i \) and any \( i' \) such that \( i' > i \), we let \([A]_{i'}\) be the induced set in \( \Omega_{i'}\):

\[
[A]_{i'} = \bigcup_{T \in A} [T]_{i'} \quad \text{for any } A \subset \Omega_{i'}.
\]

We let \([A_i]_{i'}\) be the collection of subsets of \( \Omega_{i'} \) induced by \( A_i \):

\[
[A_i]_{i'} = \bigcup_{A \in A_i} \{[A]_{i'}\}.
\]

Note that \([ [A_i]_{i'} ] = [A_i] \).

According to our definition of \( \mathcal{A}_\infty \), every element of \( \mathcal{A}_\infty \) is of the form \([A] \) where \( A \in \mathcal{A}_i \) for some \( i \). We take two arbitrary elements \([A_1] \) and \([A_2] \) of \( \mathcal{A}_\infty \) and assume, without loss of generality, that \( A_1 \in \mathcal{A}_{i_1} \) and \( A_2 \in \mathcal{A}_{i_2} \) with \( i_2 \leq i_1 \). Since \( \mathcal{A}_{i_1} \) is the collection of all subsets of \( \Omega_{i_1} \), and since \([A_2]_{i_1} \) is a subset of \( \Omega_{i_1} \), we have: \( A_1 \cup [A_2]_{i_1} \in \mathcal{A}_{i_1} \), and therefore \([A_1 \cup [A_2]_{i_1}] \in \mathcal{A}_\infty \). But \([A_1 \cup [A_2]_{i_1}] = [A_1] \cup [A_2] = [A_1] \cup [A_2] \). We have thus shown that from \([A_1], [A_2] \in \mathcal{A}_\infty \) it follows that \([A_1] \cup [A_2] \in \mathcal{A}_\infty \). Moreover, \( A_1^c \in \mathcal{A}_{i_1} \) and therefore \([A_1]^{c} = [A_1]^c \in \mathcal{A}_\infty \). So, \( \mathcal{A}_\infty \) is an algebra.

(ii) *Proof of the fact that \( \bar{P} \) is a probability measure on \( \mathcal{A}_\infty \)*

By definition, \( \bar{P}([A]) \geq 0 \) for any \([A] \in \mathcal{A}_\infty \). We also have \( \bar{P}(\Omega) = \bar{P}(\Omega_0) = 1 \). We now demonstrate that \( \bar{P} \) is finitely additive. As above, let \([A_1], [A_2] \in \mathcal{A}_\infty \), with \( A_1 \in \mathcal{A}_{i_1} \) and \( A_2 \in \mathcal{A}_{i_2} \) where \( i_2 \leq i_1 \).
Assume that \([A_1]\) and \([A_2]\) are disjoint. Then
\[
\tilde{\mathbb{P}}(\{A_1 \cup A_2\}) = \tilde{\mathbb{P}}(\{A_1 \cup A_2\}) = \tilde{\mathbb{P}}(\{A_1 \cup \{A_2\}_{i_1}\})
= P_{i_1}(A_1 \cup \{A_2\}_{i_1}) + P_{i_1}(\{A_2\}_{i_1})
= P_{i_1}(A_1) + P_{i_2}(A_2) = P(A_1) + \tilde{\mathbb{P}}(A_2).
\]

To prove that \(\tilde{\mathbb{P}}\) is not only finitely additive but also countably additive on \(\mathcal{A}_\infty\), we need to show that for any set \(B \in \mathcal{A}_\infty\) which is the union of a countably infinite collection of disjoint nonempty sets \([A_1], [A_2], \ldots \in \mathcal{A}_\infty\), we have: \(\tilde{\mathbb{P}}(B) = \tilde{\mathbb{P}}(\{A_1\}) + \tilde{\mathbb{P}}(\{A_2\}) + \ldots\). Since the number of these sets is infinite but each \(\mathcal{A}_i\) is a finite collection, for any one \(\mathcal{A}_i\) there exists a set \(\mathcal{A}_n\) such that \([A_n]\) is not an element of \([A_i]\). Consequently, there is no \(i\) for which the infinite union \(B = \{A_1\} \cup \{A_2\} \cup \ldots\) is an element of \([A_i]\). Therefore, the infinite union \(B\) cannot belong to \(\mathcal{A}_\infty\). The issue of countable additivity of \(\tilde{\mathbb{P}}\) on \(\mathcal{A}_\infty\) is therefore moot, and so \(\tilde{\mathbb{P}}\) is a probability measure on \(\mathcal{A}_\infty\).

**Proof of the Center Recursion Formulas, Proposition 3**

To prove the recursion formula (19), suppose that a tree \(T \in \Omega_u\) has a vertex \(\alpha\) which dominates \(\sqcup_{pq}\) where \(p \neq q\). We use \(\beta\) and \(\gamma\) to denote the first and second child of \(\alpha\), respectively, and suppose that the production rule applied at \(\alpha\) is the following: \(j \frac{h}{k, \ell} \). The latter supposition is equivalent to assuming that \(x_{\alpha} = j, x_\beta = k, x_\gamma = \ell\), and that there exists an integer \(d\) such that \(\sqcup_{p,(d,q_2)}\) is the yield of \(\beta\) and \(\sqcup_{(d+1,p_2),q}\) is the yield of \(\gamma\). We then have
\[
c^j_{pq}(u, T, \alpha) = P_{\prod}(j \frac{h}{k, \ell})c^k_{p,(d,q_2)}(u, T, \beta)c^\ell_{(d+1,p_2),q}(u, T, \gamma),
\]
(34)
as a direct consequence of Eq. (13). If a vertical production rule \(j \frac{v}{k, \ell}\) were applied at \(\alpha\), we would similarly have:
\[
c^j_{pq}(u, T, \alpha) = P_{\prod}(j \frac{v}{k, \ell})c^k_{p,(q_1,d)}(u, T, \beta)c^\ell_{(p_1,d+1),q}(u, T, \gamma).
\]
(35)
According to our definition of the center variable \(c^j_{pq}(u)\) in Eq. (14), the sum of (34) and (35) over all \(T_\alpha\) produces \(c^j_{pq}(u)\) in the lefthand side. To calculate the righthand side, we observe that knowing \(T_\alpha\) is equivalent to knowing the production at \(\alpha\), the left subtree \(T_\beta\), the right subtree \(T_\gamma\), and the split location \(d\). Therefore, the sum of (34) and (35) over all \(T_\alpha\) is the sum over all allowed split locations, all allowed \(k\) and \(\ell\), and all allowed subtrees \(T_\beta\) and \(T_\gamma\):
\[
c^j_{pq}(u) = \sum_{d=p_1}^{q_1-1} \sum_{k \in \mathcal{N}} \sum_{\ell \in \mathcal{N}} \sum_{T_\beta} \sum_{T_\gamma} P_{\prod}(j \frac{h}{k, \ell})c^k_{p,(d,q_2)}(u, T, \beta)c^\ell_{(d+1,p_2),q}(u, T, \gamma).
\]

January 30, 2003
+ \sum_{d=p_2}^{q_2-1} \sum_{k \in N} \sum_{\ell \in N} \sum_{T_{\beta}} \sum_{T_{\gamma}} P_{\text{prod}}(j \rightarrow k, \ell) c_{p,(q_1,d)}^{k}(u, T, \beta) c_{(p_1,d+1),q}^{\ell}(u, T, \gamma) \\
= \sum_{d=p_1}^{q_1-1} \sum_{k \in N} \sum_{\ell \in N} P_{\text{prod}}(j \rightarrow h, k, \ell) \left[ \sum_{T_{\beta}} c_{p,(d,q_2)}^{k}(u, T, \beta) \right] \cdot \left[ \sum_{T_{\gamma}} c_{(d+1,p_2),q}^{\ell}(u, T, \gamma) \right] \\
+ \sum_{d=p_2}^{q_2-1} \sum_{k \in N} \sum_{\ell \in N} P_{\text{prod}}(j \rightarrow v, k, \ell) \left[ \sum_{T_{\beta}} c_{p,(q_1,d)}^{k}(u, T, \beta) \right] \cdot \left[ \sum_{T_{\gamma}} c_{(p_1,d+1),q}^{\ell}(u, T, \gamma) \right],
resulting in Eq. (19).

To derive the base case formula Eq. (20), let $\alpha$ be the internal vertex which dominates pixel $p$, and suppose that the rule applied at $\alpha$ is $j \rightarrow u$. Then the only possible $T_\alpha$ is a tree consisting of two vertices, with state $j$ at the root vertex and state $u$ at the leaf vertex. Therefore,

$$c_{pp}^j(u) = c_{pp}^j(u, T, \alpha) = P_{\text{prod}}(j \rightarrow u),$$

which gives Eq. (20).

**Proof of the EM Update Formulas, Proposition 6**

Using our definition (5) of the probability distribution $P$, we can write the $Q$ function as follows:

$$Q(G, G^n) = \sum_{i=1}^{l} \sum_{T \in \Omega_{u^i}} P(T|u^i, G^n) \log P_{\text{root}}(x_\rho) + \sum_{i=1}^{l} \sum_{T \in \Omega_{u^i}} \sum_{\alpha \in \mathcal{V}_{\text{int}}} P(T|u^i, G^n) \log P_{\text{prod}}(A_\alpha). \quad (36)$$

In order to maximize this over $P_{\text{root}}$ and $P_{\text{prod}}$, we need to maximize the first term over $P_{\text{root}}$ and the second term over $P_{\text{prod}}$. We therefore have two constrained maximization problems with constraints given by the normalization equations (3) and (4). We solve these problems using Lagrange multipliers.

We rewrite the first term as follows:

$$\sum_{i=1}^{l} \sum_{T \in \Omega_{u^i}} P(T|u^i, G^n) \log P_{\text{root}}(x_\rho) = \sum_{i=1}^{l} \sum_{j \in N} \sum_{T \in \Omega_{u^i}^j} P(T|u^i, G^n) \log P_{\text{root}}(j)$$

$$= \sum_{i=1}^{l} \sum_{j \in N} P(\Omega_{u^i}^j|u^i, G^n) \log P_{\text{root}}(j)$$

$$= \sum_{i=1}^{l} \sum_{j \in N} P(\Omega_{u^i}^j|u^i, G^n) \log P_{\text{root}}(j).$$
where $\Omega^j_{\cdot i} = \Omega_{\cdot i} \cap \Omega^j$ is the set of all elements of $\Omega_{\cdot i}$ with root state $j$. Denoting a Lagrange multiplier by $t$, we therefore obtain, for any $j \in \mathcal{N}$:

$$
\frac{\partial}{\partial P_{\text{root}}(j)} \left[ \sum_{i=1}^I \sum_{j'} P(\Omega^{j'}_{\cdot i}, G^n) \log P_{\text{root}}(j') + t \left( 1 - \sum_{j'} P_{\text{root}}(j') \right) \right] = 0
$$

(37)

$$
\frac{\sum_{i=1}^I P(\Omega^{j}_{\cdot i}, G^n)}{P_{\text{root}}(j)} - t = 0
$$

(38)

Multiplying (37) by $P_{\text{root}}(j)$, summing over $j$, and using the normalization equation (4), we get:

$$
\sum_{j=1}^I \sum_{i=1}^I P(\Omega^{j}_{\cdot i}, G^n) = \sum_j P_{\text{root}}(j) t
$$

$$
I = t.
$$

We substitute this into (38) and apply the Bayes rule in order to get an expression in terms of quantities computable with center variables:

$$
P^{n+1}_{\text{root}}(j) = \frac{1}{I} \sum_{i=1}^I P(\Omega^{j}_{\cdot i}, G^n) = \frac{1}{I} \sum_{i=1}^I \frac{P(\Omega^{j}_{\cdot i}, G^n) P_{\text{root}}(j)}{P(\Omega^{j}_{\cdot i}, G^n)} = \frac{1}{I} \sum_{i=1}^I \frac{P(\Omega^{j}_{\cdot i}, G^n) P_{\text{root}}(j)}{P(\Omega^{j}_{\cdot i}, G^n)}
$$

We use $\#(T)$ and $\#_j(T)$ to denote the number of occurrences of production $\Lambda$ and state $j$, respectively, in a tree $T$. We now rewrite the second term of the $Q$ function (36) as follows:

$$
\sum_{i=1}^I \sum_{T \in \Omega_{\cdot i}} \sum_{\alpha \in V_{\text{int}}} P(T|u^i, G^n) \log P_{\text{prod}}(\Lambda_\alpha) = \sum_{i=1}^I \sum_{j \in \mathcal{N}, \Lambda \in \mathcal{P}_{\cdot j}, T \in \Omega_{\cdot i}} \sum P(T|u^i, G^n) \#_{\Lambda}(T) \log P_{\text{prod}}(\Lambda).
$$

For each nonterminal state $j$, we use Lagrange multiplier $t_j$:

$$
\frac{\partial}{\partial P_{\text{prod}}(\Lambda)} \left[ \sum_{i=1}^I \sum_{j' \in \mathcal{N}, \Lambda' \in \mathcal{P}_{\cdot j'}} \log P_{\text{prod}}(\Lambda') \sum_{T \in \Omega_{\cdot i}} P(T|u^i, G^n) \#_{\Lambda'}(T) 
$$

$$
+ \sum_{j' \in \mathcal{N}} t_{j'} \left( 1 - \sum_{r' \in \mathcal{P}_{\cdot j'}} P_{\text{prod}}(\Lambda') \right) \right] = 0
$$

$$
\sum_{i=1}^I \frac{1}{P_{\text{prod}}(\Lambda)} \sum_{T \in \Omega_{\cdot i}} P(T|u^i, G^n) \#_{\Lambda}(T) - t_j = 0
$$
This results in the following update equation for the production probabilities:

\[
\mathbf{P}_{\text{prod}}^{n+1}(\Lambda) = \frac{1}{t_j} \sum_{i=1}^{I} \sum_{T \in \Omega_{u_i}} \mathbf{P}(T|\mathbf{u}^i, \mathcal{G}^n) \mathbf{#}(T)
\]

\[
t_j = \sum_{\Lambda \in \mathcal{T}^j} \sum_{i=1}^{I} \sum_{T \in \Omega_{u_i}} \mathbf{P}(T|\mathbf{u}^i, \mathcal{G}^n) \mathbf{#}(T) = \sum_{i=1}^{I} \sum_{T \in \Omega_{u_i}} \mathbf{P}(T|\mathbf{u}^i, \mathcal{G}^n) \mathbf{#}_j(T)
\]

To calculate the inner sum of the numerator, first suppose that \( T \in \Omega_{u_i} \) is a tree whose vertex \( \alpha \) dominates \( \square_{pq} \), for some \( p \) and \( q \) with \( p \neq q \). Let us call the children of \( \alpha \) \( \beta = C_1(\alpha) \) and \( \gamma = C_2(\alpha) \) and suppose that the production rule applied at \( \alpha \) is \( j \overset{h}{\rightarrow} k, \ell \). The latter supposition is equivalent to assuming that \( x_\alpha = j, x_\beta = k, x_\gamma = \ell \), and that there exists \( d \) such that \( \square_{p,(d,q_2)} \) is the yield of \( \beta \) and \( \square_{(d+1,p_2),q} \) is the yield of \( \gamma \). We then have, using Eqs. (13,16),

\[
\mathbf{P}(T) = s_{pq}^j(\mathbf{u}^i, T, \alpha) \mathbf{P}_{\text{prod}}^n(j \overset{h}{\rightarrow} k, \ell) c_{p,(d,q_2)}^k(\mathbf{u}^i, T, \beta) c_{(d+1,p_2),q}^\ell(\mathbf{u}^i, T, \gamma).
\]

The inner sum of the numerator of (39) can be obtained by summing this over all \( T_\beta, T_\gamma, T_\alpha, d, p, \) and \( q \), to yield the expression in the numerator of (27). Vertical and terminal productions are handled similarly, to result in the numerators of (28) and (29), respectively. The inner sum in the denominator of (39) is also handled similarly, to result in the denominators of (27-29).
