Abstract

The paper investigates how to extend, in a general way, compilation algorithms for subsets of the programming language Lucid, so as to handle a substantially enlarged class of programs. In particular, given an algorithm $\alpha$ which compiles correctly simple programs satisfying the syntactic restriction $R$, we show how to extend $\alpha$ and $R$ to compile programs which use a nesting construct. The technique does not depend on the particulars of $\alpha$ and $R$, although the size of the larger class depends on $R$. It constitutes an example of a compiler structuring which admits a modular correctness proof of the compiler.
1. Introduction

Proving a compiler correct is an important and non-trivial problem. Since most programs are written in a higher level language which has to be compiled, a correct compiler is a necessary part for obtaining correct results independent of a proof of the source program. The problem is amplified by the fact that very large programs, and compilers, are often just that, may contain subtle mistakes which remain undetected for a long time.

The proof of a compiler requires a formal model of the semantics of the source and the object language which has to be suited both for proof purposes and for good implementation strategies. Without such models, a proof will be awkward and difficult. Perhaps for these reasons previous work on compiler correctness has dealt with languages which permit an elegant mathematical model [7, 9], or for small languages isolating a few of the constructs present in imperative languages [5, 8, 10].

We illustrate in this paper an approach to compiler correctness which reduces the complexity of the task by modularizing the proof. Morris [10] seems to have been the first to suggest this idea. Since analogous approaches to programming have been accepted principles of software design for quite some time now, it is perhaps not surprising that proof modularization appears to be an attractive method.

The source language under consideration is Lucid [1, 2, 3], a proof-oriented programming language. We define the basic language and isolate the subset of simple programs. Assuming the existence of an algorithm
which correctly compiles those simple programs which satisfy a syntactic restriction \( R \), we show how \( \mathcal{A} \) may be extended to compile the larger language by incorporating language constructs not allowed in simple programs.

Existence of such algorithms may be assumed because of [6]. As only general assumptions are made about \( \mathcal{A} \) and \( R \), however, our results can be used to extend any conceivable algorithm \( \mathcal{A} \) which works correctly for a formulated syntactic restriction \( R \). In fact, the results also apply to interpreters such as, for example, the one reported in [4].

This degree of generality can be accomplished, because the added language constructs admit the decomposition of the source program into a collection of simple programs, related by known properties of the constructs. The decomposition result is proved first, and from it the extension strategy is derived.

The paper assumes some familiarity with the language. [1, 2, 3] are all good sources for studying Lucid, and [6] gives a specific instance of the extension technique presented here.
2. Lucid Programs and Proper Restrictions

Assuming the notation and definitions of [2], we fix in the following a particular Lucid system by choosing, without loss of generality, a standard alphabet Σ, a standard Ξ structure S whose Comp(S) structure is C, and a set V of variables, and note that the results of this paper are valid in any Lucid system. As in [2], U denotes the range of S, i.e. a set of values.

G is the set of operation symbols in Σ, F = {first, next, fby, asc, latest, latest⁻¹} the set of Lucid functions, E the set of (Σ ∪ F) terms without quantifiers and the symbol =, E₀ the subset of (Σ ∪ F) terms without quantifiers, =, latest, and latest⁻¹. N denotes the set of natural numbers, N the set of infinite sequences over N.

U is the set of all functions from N into U. Recall the definition of Comp(S):

**Definition** If S is a standard Ξ structure, then Comp(S) is the unique (Σ ∪ F) structure C which extends (S_N) to the larger alphabet as follows:

For \( \bar{t} = t_0 t_1 t_2 \ldots \) in N, \( \alpha, \beta, \ldots \) in U

1. \( (\omega \ (\alpha, \beta, \ldots))_{\bar{t}} = \omega_{\bar{t}} (\alpha, \beta, \ldots) \) for all \( \omega \) in G
2. \( (\text{first}_{\bar{t}} (\alpha))_{\bar{t}} = \alpha_{t_0 t_1 t_2 \ldots} \)
3. \( (\text{next}_{\bar{t}} (\alpha))_{\bar{t}} = \alpha_{t_0+1 t_1 t_2 \ldots} \)
4. \( (\alpha \ \text{fby}_{\bar{t}} \beta)_{\bar{t}} = \begin{cases} \alpha_{t_0} t_1 t_2 \ldots & \text{if } t_0 = 0 \\ \beta_{t_0-1} t_1 t_2 \ldots & \text{otherwise} \end{cases} \)
if there exists a unique \( s \) such that

\[
(\alpha \text{ assume } \beta)^\xi = \begin{cases} 
\{ \text{if there exists a unique } s \text{ such that } \\
\beta_{st_1 t_2} \text{ is true and } \beta_{st_2 t_2} \text{ is false} \\
\text{for all } r < s; \\
\text{undefined otherwise}
\end{cases}
\]

\[
(\text{latest}_c (\alpha))^\xi = \alpha_{t_1 t_2}.
\]

\[
(\text{latest}^{-1}_c (\alpha))^\xi = \alpha_0 t_0 t_1 t_2.
\]

**Definition**  A Lucid program \( P \) is a set of \((V,F)\) terms of the form \( v = \phi_v \) where \( v \) is in \( V \) and \( \phi_v \) is in \( E \), and such that every variable \( v \) in \( P \) is defined in this way at most once, and the variable input is not defined.

If, furthermore, every term \( \phi_v \) is in \( E_0 \), then \( P \) is a *simple program*.

The *solution* of a program \( P \) is the minimal (least defined) \( C - \) interpretation \( \sigma \) which, for a fixed interpretation \( \alpha \) of input, satisfies \( P \). Every Lucid program has a unique solution [2].

In order to enhance the clarity of Lucid as a programming language, certain syntactic constructs for structuring programs have been introduced in [3]. We intend to study the nature of one of these constructs, the *compute clause*, defined by a syntactic transformation which changes programs using compute clauses into programs of the form defined above. The clause has the following syntax

```
compute (variable) using (variable list)
(set of definitions)
end
```

and is considered a definition of the variable following the word compute, called the *subject* of the clause. The variables in the (variable list)
are the global variables, the \( \langle \text{set of definitions} \rangle \) is the body of the
clause. All variables which occur in the body of the clause and are not
global variables, are local variables of the clause. The special variable
'result' is always a local variable and refers to the subject of the clause.

A compute clause is equivalent to the set of terms \( v = \phi_v \) obtained
by

1. Renaming all local variables except result with new names not
occurring elsewhere in the program,
2. Replacing every global variable \( X \) by \( \text{latest } X \) in the body,
3. Replacing "result = \( \phi \)" by "\( Y = \text{latest}^{-1}(\phi) \)" where \( Y \) is the subject,
and deleting the compute variable using \( \langle \text{variable list} \rangle \) and end.

Example The following is a compute clause
\[
\text{compute } D \text{ using } M, N \\
L = M \text{ fby } L + N \\
\text{result } = L \text{ eq } N \text{ asg } L \geq N \\
\text{end}
\]
and is equivalent to
\[
L = \text{latest } M \text{ fby } L + \text{latest } N \\
D = \text{latest}^{-1}(L \text{ eq } \text{latest } N \text{ asg } L \geq \text{latest } N)
\]
It defines \( D \) to be the predicate "\( M \) divides \( N.\)"

We can now redefine the syntax of programs. A basic assertion is a
(\( \Sigma \omega F \)) term of the form \( v = \phi_v \) where \( \phi_v \) is in \( E \). Then

\[
\langle \text{program} \rangle \quad ::= \text{compute output } \langle \text{globals} \rangle \langle \text{clause body} \rangle
\]
\[
\langle \text{globals} \rangle \quad ::= \langle \text{empty} \rangle
\]
\[
\langle \text{empty} \rangle \quad ::= \text{using } \langle \text{variable list} \rangle
\]
\[
\langle \text{clause body} \rangle \quad ::= \text{end}
\]
\[
\langle \text{variable list} \rangle \quad ::= \langle \text{variable} \rangle
\]
\[
\langle \text{variable} \rangle \quad ::= \langle \text{variable list} \rangle \text{, } \langle \text{variable} \rangle
\]
\[
\text{<assertion>} ::= \text{<basic assertion>} \\
\text{| <clause>}
\]
\[
\text{<clause>} ::= \text{compute <variable> <globals> <clause body>}
\]

where, in addition, the <globals> of output is either empty or "using input", every variable is defined at most once, either by a clause or a basic assertion, and the expression in each result definition is quiescent (see [2], Sec. 4.1), i.e. behaves as a constant.

A simple program is a <program> without any nested clause.

Let \( \mathcal{R} \) be a set of syntactic constraints on simple programs. \( \mathcal{R} \) is a proper restriction if it is decidable whether or not a simple program satisfies \( \mathcal{R} \), and if there exists an algorithm \( \mathcal{A} \) which correctly compiles simple programs satisfying \( \mathcal{R} \).

We study how to extend \( \mathcal{A} \) and \( \mathcal{R} \) to programs containing nested compute clauses, after deriving certain properties of variables defined by compute clauses.
3. Properties of Compute Clauses

In a compute clause all global variables referenced are quiescent, i.e., satisfy $\text{first} \ G = G$, because of the latest implicitly applied to each global variable $G$. Therefore, only the current component values of global variables need to be known throughout the evaluation of the clause. Hence the global environment is 'frozen' inside a clause.

Assume that the compute clause $B_2$ is nested within another compute clause $B_1$. We prove that within $B_1$ the subject variable of $B_2$ may be considered to be defined by a point-wise operation $f$ with arguments $G^{(1)}$, ..., $G^{(r)}$ which are precisely the global variables of $B_2$.

**Theorem 3.1** Let $R$ be the subject of the compute clause $B_2$ nested in $B_1$ with global variables $G^{(1)}$, ..., $G^{(r)}$. Then, in the clause $B_1$,

$$R = f(G^{(1)}, \ldots, G^{(r)})$$

$$\text{first } R = f(\text{first } G^{(1)}, \ldots, \text{first } G^{(r)})$$

$$\text{next } R = f(\text{next } G^{(1)}, \ldots, \text{next } G^{(r)})$$

for some function $f$ of $r$ arguments.

**Proof** By induction on the nesting structure of clauses.

**Basis** Assume that $B_2$ does not contain any nested clauses. Let $G^{(1)}$, ..., $G^{(j)}$ be those global variables of $B_2$ which are local to $B_1$, and $G^{(j+1)}$, ..., $G^{(r)}$ those which are global to $B_1$ as well. In removing the clause structure from the program, there are $i_k$ many latest applied to the $G^{(k)}$ in expressions in the body of $B_2$, transforming the $G^{(k)}$ into $\tilde{G}^{(k)}$, i.e.,

$$\tilde{G}^{(k)} = \text{latest } L^{(k)} G^{(k)}.$$ 

The interpretation $|H|$ of every expression $H$ in $B_2$ may be considered a function $f_H$ of the $\{\tilde{G}^{(k)}\}$. 
Let \( t = t_0 t_1 t_2 \ldots \) be in \( N^N \), then
\[
(|\mathcal{R}|)_t = (f_H)_t (\langle |g^{(1)}| \rangle_t, \ldots, \langle |g^{(r)}| \rangle_t)
\]
Since \textit{latest} and \textit{latest}^{-1} are the only operations manipulating the \( t_1 t_2 \ldots \)
all of which are applied to the \( G^{(k)} \), \( f_H \) does not depend on the \( t_1 t_2 \ldots \)
and varies with \( t_0 \) only:
\[
(f_H')_0 = (f_H')_t_0
\]
In particular, because of its quiescence, for the result expression \( E \) we have
\[
(f_E)_t = (f'_E)_t_0 = f_E
\]
Therefore, in \( B_1 \),
\[
(|\mathcal{R}|)_{t_1 t_2 \ldots} = (\text{latest}^{-1} (f_E (\langle |g^{(1)}| \rangle)_{t_1 t_2 \ldots})\ldots,
= (f_E (\langle |g^{(1)}| \rangle)_{0 t_1 t_2 \ldots} \ldots, (\langle |g^{(r)}| \rangle)_{0 t_1 t_2} \ldots)
\]
Let \( \bar{G}^{(k)} = \text{latest} \ G^{(k)} \), then
\[
(|\mathcal{R}|)_{t_1 t_2 \ldots} = f_E (\langle |\bar{g}^{(1)}| \rangle_{t_1 t_2 \ldots}, \ldots, (\langle |\bar{g}^{(r)}| \rangle_{t_1 t_2} \ldots)
\]
Observe now that in removing the clause structure, the variables \( \bar{G}^{(k)} \)
have \( i_{k-1} \) many \textit{latest} applied in expressions in the body of \( B_1 \), hence
are transformed into the \( \bar{G}^{(k)} \). From this the theorem follows.

\textbf{Induction Step} Follows from the induction basis after all nested clauses
have been replaced by the corresponding pointwise equations.

\textbf{Corollary 3.2} Let \( B \) be a compute clause all of whose global vari-
ables are quiescent. Then the subject variable of \( B \) is quiescent in the
containing block.

\textbf{Proof} Straight-forward.
We state the corollary because it can be used to define an optimizing transformation which reduces the nesting level of such clauses. This corresponds to a well-known compiler optimization technique known from conventional languages as moving invariant computations out of loops.

Note also, that because global variables of $B_2$ which are not local to the containing clause $B_1$ are quiescent in $B_1$, the function $f$ defining the subject of $B_2$ depends in $B_1$ only on those global variables of $B_2$ which are local to $B_1$. 
4. Extension of Compilation Algorithms

We investigate now how to modify a given proper restriction \( R \) and the associated compiling algorithm \( \mathcal{A} \) so as to compile programs with nested compute clauses.

**Definition** The evaluation of \( (|X|)_\xi \) is unsafe if potentially \( (|X|)_\xi \) is undefined, i.e., may correspond to a non-terminating computation. If \( f \) is a pointwise operation and if \( (|f(X, Y, ...|)_\xi \) is potentially undefined when each of the \( (|X|)_\xi, (|Y|)_\xi \) are not, then \( f \) is unsafe.

Note that nested compute clauses usually correspond to unsafe pointwise computations. However, even in the case of simple programs, the interaction of non-strict and unsafe evaluations already gives rise to the 'delayed evaluation rule' for Lucid (the term is due to Vuillemin [12]), as demonstrated by the following example. In essence, delayed evaluation means that \( (|X|)_\xi \) is not to be evaluated, unless the particular value configuration requires this value.

**Example 4.1** Consider the following simple program:

\[
\text{output} = X \quad \text{as} \quad Y \quad \text{at first input}
\]
\[
R = 1 \quad \text{as} \quad \text{input eq next input}
\]
\[
P = \text{input} \quad \text{eq} \quad 1
\]
\[
X = 0 \quad \text{fby} \quad \text{(if P then X+R else Y)}
\]
\[
Y = 1 \quad \text{fby} \quad 2\cdot Y
\]

Because of the non-strict computation of next X in conjunction with the unsafe evaluation of R, and because only a specific \( \xi \) component of X is needed to compute output, the evaluation of both X and R should be delayed until demanded for specific \( \xi \) values.
Either $R$ severely curtails the interplay of non-strict and unsafe evaluations, or the algorithm $\mathcal{A}$ is sophisticated enough to handle such situations. In either case, the extension of $\mathcal{A}$ to the larger class of programs will be seen to require fairly standard methods in addition to the techniques of $\mathcal{A}$.

A proper restriction $R$ analyzes syntactically a set of terms of the form $v = \phi_v$, where $\phi_v$ is in $E_0$. Given a program $P$, we associate with every compute clause $B_j$ in $P$ a set $P_j$ of terms of the above form:

Replace every compute clause $B_j$ with subject $X$ and global variables $g(1)...g(r)$ which is directly nested in $B_j$ (i.e. such that $X$ is a local variable of $B_j$) by the term $X = f_X(g(1),...,g(r))$, where $f_X$ represents a non-strict and unsafe pointwise operation. No other assumptions about $f_X$ are made unless derivable syntactically by $R$ from the final set $P_j$ of terms. Also, replace every reference to a global variable $G$ of $B_j$ by a symbolic constant. The set $P_j$ is now the transformed body of $B_j$ which is evidently of the desired form, and is called the simple program associated with $B_j$.

If every simple program associated with each clause of $P$ satisfies $R$, then $P$ satisfies $R'$, the proper restriction derived from $R$. It is easy to see that the class of programs satisfying $R'$ properly includes all simple programs satisfying $R$.

Consider the algorithm $\mathcal{A}$ associated with $R$. Observe that $\mathcal{A}$ is either capable of implementing the delayed evaluation rule to the degree required by $R$, thus can generate code evaluating a variable on demand for a particular $t$ in $N^N$, or deals with programs in which delayed evalu-
ulation is required only for variables with safe evaluations. Define an
algorithm $\mathcal{U}'$, the extension of $\mathcal{U}$, as follows.

$\mathcal{U}'$ compiles each compute clause $B_i$ in the source program $\mathcal{P}$ into a
procedure $\tilde{B}_i$ which is to return the value of the result expression for
a particular $\tilde{\xi}$ in $\mathcal{N}^N$ when called. Because of Theorem 3, this is always
possible. The body of $\tilde{B}_i$ is compiled by $\mathcal{U}'$ in exactly the same way in
which $\mathcal{U}$ compiles $P_i$ with the following exceptions.

A reference to a variable $G$ global to $B_i$ is compiled into a call of
a parameter procedure $p$ which is to evaluate the latest value of $G$ in the
environment of its definition (usually the calling environment). Furthermore,
since $G$ is quiescent in $B_i$, more efficiency can be gained by compiling
code which calls $p$ at most once during each activation of $\tilde{B}_i$. Methods for
this are routine.

A clause $B_j$ with subject $X$ and global variables $G^{(1)} \ldots G^{(r)}$ which
is directly nested in $B_i$ is compiled in stages. For every one of the $G^{(k)}$
a parameter procedure $p_k$ is compiled. Depending on the properties of the
$G^{(k)}$ and the capabilities of $\mathcal{U}$, the following cases arise:

1. $G^{(k)}$ is global to $B_i$ as well. The code for $p_k$ is the code for refer-
encing a global variable of $B_i$ as described above, i.e. a call to
another parameter procedure compiled in the clause containing $B_i$.

2. $G^{(k)}$ is local to $B_i$ and has a safe evaluation. $\mathcal{U}$ may have elected
to evaluate $G^{(k)}$ always (making $f_K$ depend on $G^{(k)}$ strictly); then
$p_k$ references that value. Otherwise $\mathcal{U}$ can implement a delayed e-
valuation of $G^{(k)}$. In that case $p_k$ will contain code evaluating
$G^{(k)}$. 

(3) \( g^{(k)} \) is unsafe. Since \( P \) satisfies \( R \), \( \mathcal{U} \) can compile a delayed evaluation of \( g^{(k)} \). This evaluation is the procedure \( p_k \).

Finally, the code for evaluating \( (\lambda x)_{\xi} \) is a call of \( B_j \).

In this way, \( \mathcal{U}' \) compiles \( P \) into a set of procedures. A standard driving program is added which calls the procedure for the outermost clause requesting the evaluation of output. See [6] for a specific example of this extension technique.

**Lemma 4.1** Let \( R \) be a proper restriction, \( R' \) the proper restriction derived from \( R \). Then \( R' \) is decidable.

**Proof** Evident from the construction of \( R \).

Let \( \sigma \) be the solution of the program \( P \) and \( [x]_{\sigma} \) the interpretation of \( X \) in \( P \) according to \( \sigma \). Assume that \( P \) satisfies \( R' \). The code \( W \) compiled by \( \mathcal{U}' \) for \( P \) consists of procedures \( B_i \) compiled from the clauses \( B_i \) of \( P \), and parameter procedures \( p_{ik} \) evaluating \( (\lambda (k))_{\sigma} \), for variables \( G^{(k)} \) global to \( B_i \).

**Lemma 4.2** Let \( \pi' \) be the code compiled by \( \mathcal{U}' \) for the program \( P \) which satisfies \( R' \). If every parameter procedure \( p_{ik} \) correctly returns \( (\lambda (k))_{\sigma} \), then the procedure \( B_i \) compiled for clause \( B_i \) with subject \( X \) correctly evaluates \( (\lambda x)_{\sigma} \).

**Proof** (Induction on the nesting structure of clauses)

**Basis** Assume that \( B_i \) contains no nested clauses. Since the parameter procedures called by \( B_i \) correctly evaluate \( (\lambda (k))_{\sigma} \) by assumption, correctness follows from Theorem 3.1 and the correctness of \( \mathcal{U} \).

**Stop** Equally straightforward.
Consequently, the correctness of $CL'$ can be established by showing the correctness of the parameter procedures. Since no specific properties of $CL$ and $R$ can be assumed, this must be proved by a reduction to the correctness of $CL$.

**Theorem 4.3** Let $\pi$ be the program compiled by algorithm $CL'$ for the source program $P$ satisfying $R'$. Given a clause $B_i$ in $P$, the procedure $B_i$ is correct provided the parameter procedures $p_1 \ldots p_g$ of variables global to $B_i$ are correct.

**Proof** (By induction on the nesting structure of clauses)

**Basis** $B_i$ does not contain any nested clauses. Since the $p_1 \ldots p_g$ are the only parameter procedures called by $B_i$, the theorem follows from Lemma 4.2.

**Step** Assume the theorem is true for all clauses $B_j$ not containing other clauses nested beyond depth $d$. Let $B_i$ be a clause which does not contain other clauses nested beyond depth $d+1$. We have to show that the correctness of $p_1 \ldots p_g$ implies the correctness of the parameter procedures $q_1 \ldots q_r$ compiled to evaluate variables global to clauses directly nested in $B_i$.

The correctness of the $p_1 \ldots p_g$ directly implies the correctness of those $q_k$ which are to evaluate variables which are global to $B_i$ as well. The correctness of the remaining procedures $q_k$ evaluating local variables is seen by considering the associated simple program $P_i$.

Recall that every clause with subject $Y$ local to $B_i$ is defined in $P_i$ by

$$Y = f_Y (G^{(1)}, G^{(2)}, \ldots)$$

$P_i$ satisfies $R$ because $P$ satisfies $R'$. By Lemma 4.2 and the induction
hypothesis, $B_j$ correctly implements the operation $f_j$. Correctness of all
sequence evaluations in $P_1$ now follows from the correctness of $\mathcal{L}$, and
from it the correctness of the procedures $\varphi_k$.

**Corollary 4.4** The code $\pi$ compiled for $P$ satisfying $\mathcal{K}$ correctly
evaluates $|\text{output}|_\sigma$.

**Proof** Since input is the only global variable a program may have,
it suffices to show that the parameter procedure to evaluate it is correct.
This is true since input is also global to simple programs, hence follows
from the correctness of $\mathcal{L}$.

This establishes the correctness of $\mathcal{L}'$ as extension of $\mathcal{L}$. The re-
sult originates from the fact that $P$ can be decomposed into the simple
program $P_1$ and that the individual procedures generated are coordinated
by the same techniques which $\mathcal{L}$ employs to coordinate the evaluation of
non-strict and unsafe computations. $\mathcal{K}'$ ensures that $\mathcal{L}'$ is not overtaxed
in this. Note, however, that the class of programs satisfying $\mathcal{K}'$ depends
in size on $\mathcal{K}$; for less restrictive conditions $\mathcal{K}$ the class is larger.
This is, of course, intuitive.
5. Conclusions

We have shown how to extend algorithms compiling simple programs to handle nested compute clauses. As the techniques for this were derived from language properties rather than particular aspects of the algorithms or their scope, our results are applicable to any compilation strategy. Of course, the 'size' of the new class of programs compilable by the extended algorithm depends on the restrictiveness of \( R \), i.e. on the degree of sophistication of the algorithm \( C \).

Of the other language constructs proposed in [3], a good candidate for a similar extension theorem would be the mapping clause, which is a generalization of the compute clause, and can be handled in essentially the same manner. For other clauses, however, it is not clear how to decompose them into simpler concepts successfully. In particular, the full generality of the transform clause is a deep challenge to compiler writers, if at all compilable.

Intuitively, we suspect that the 'orthogonality' (cf. [11]) of a construct allows the formulation of extension theorems. Since the global environment is frozen inside a compute clause, the construct serves to substitute programs for expressions in the definition of variables. Therefore, it is of advantage to structure a compiler accordingly, both from the design aspect as well as from the point of view of proving its correctness.

It should be the case, that the modularization of a program and of its proof serves to reduce the effort invested in the development of both. Research of proof strategies aiming at exploiting this should be very fruitful.
