ARTICLE INFO

Keywords:
Negative-index metamaterials
Backward electromagnetic waves
Resonant four-wave mixing and optical parametric amplification
Quantum control

The feasibility of all-optically tailored transparency of the negative-index slab, its extraordinary dependence on the intensity of the control field, absorption indices and phase-matching of the parametrically coupled counter-propagating waves is numerically simulated.

1. Introduction

Negative-index (also known as negative phase velocity or left-handed) metamaterials (NIMs) form a novel class of electromagnetic media that promises revolutionary breakthroughs in photonics [1]. Significant progress has been achieved recently in the design of bulk, multilayered, plasmonic structures [2–5]. The majority of NIMs realized to date consist of metal-dielectric nanostructures, meta-atoms, that have highly controllable magnetic and dielectric responses. The challenge, however, is that these structures are strongly lossy. The losses may originate from a number of sources. Irrespective of their origin, losses constitute a major hurdle on the way to practical realization of unique applications of these structures in optics. Therefore, developing efficient loss-compensating techniques is of paramount importance. So far, the most common approaches to compensating losses in NIMs are related with the possibility to embed amplifying centers in the host matrix. The amplification is supposed to be provided through a population inversion between the levels of the embedded centers. Herein, we investigate alternative options based on coherent, nonlinear optical (NLO) energy transfer from the control optical field(s) to the signal through optical parametric amplification (OPA). Nonlinear optics in NIMs remains so far a less-developed branch of optics. On a fundamental level, the NLO response of nanostructured metamaterials is not completely understood or characterized. Nevertheless, it is well established that local-field enhanced nonlinearities can be attributed to plasmonic nanostructures, and some rough estimates of their magnitude can be made. The feasibility of crafting NIMs with strong NLO responses in the optical wavelength range has been experimentally demonstrated in Ref. [6]. Unusual properties of NLO propagation processes in NIMs, such as second-harmonic generation, three-wave mixing (TWM) and four-wave mixing (FWM) OPA, which are in a stark contrast with their counterparts in natural materials, were shown in [7–17]. Striking changes in the properties of nonlinear pulse propagation and temporal solitons [18], spatial solitons in systems with bistability [19–21], gap solitons [22], and optical bistability in layered structures including NIMs [23] were revealed. A review of some of the corresponding theoretical approaches is given in Refs. [24,25]. Herein, we describe basic principles and specific features of the proposed several techniques of compensating losses in NIMs based on nonlinear-optical propagation processes such as coherent three-wave and four-wave mixing in strongly absorbing media. Backwardness of one of the coupled waves (the signal), i.e., opposite direction of its phase velocity and energy flow which is intrinsic to NIMs, is the factor of crucial importance for the proposed techniques.

2. Compensating losses through three-wave-mixing energy-transfer from the control field to the negative-index signal

The basic idea is as follows. Three coupled optical electromagnetic waves with wave vectors \( \mathbf{k}_{1,2,3} \) co-directed along the \( z \) axis propagate through a slab of thickness \( L \) with quadratic, TWM, magnetic [8] nonlinearity \( \chi^{(2)} \). The outcomes do not change...
in the case of electric nonlinearity. Only two waves enter the slab, strong control field at \(\omega_2\) and weak signal at \(\omega_1\), which then generate a difference-frequency idler at \(\omega_3 = \omega_2 - \omega_1\). The idler contributes back to the signal through the similar TWM process, \(\omega_1 = \omega_3 + \omega_2\), and thus provides OPA of the signal. The signal is assumed negative-index, \(n(\omega_1) < 0\), and therefore backward wave (BW). This means that the energy flow \(S_1\) is antiparallel to \(k_1\) [Fig. 1(a)], which contrasts with the early proposals [26–28] and robust control field at \(\omega_3\) in the case of electric nonlinearity. Only two waves enter the slab, which is assumed homogeneous through the slab, local NLO energy conversion rate for each of the waves is proportional \(D_s = \mu_s/m_s\), \(m_s\) mismatch \(T_1\) of the slab becomes \(0\), and thus provides OPA of the signal. The signal is seen that the signal grows sharply with the approaching \(gL\), \(gL > 0\). (b) Transmission \(T_1(z = 0)\) at the ratio of the decay rates. A typical plasmonic NIM slab absorbs about 90% of light at the frequencies which are in the NL frequency-range. Such absorption corresponds to \(a_1L \approx 2.3\). The slab becomes transparent within the broad range of the slab thickness and the control field intensity if the transmission in all minimums is about or more than 1. It appeared that such robust transparency can be achieved through the appropriate adjustment of the absorption indices \(s_2 \geq s_1\) [16]. It is illustrated in Figs. 1(b)–(d). It is seen that the signal grows sharply with the approaching “geometrical” resonances, which indicates cavityless oscillations. Fig. 1(f) demonstrates another extraordinary possibility of eliminating the detrimental effect of the phase-mismatch by the modest increase of the amplitude of the control field. For \(\chi^{(2)} \approx 80\ pm/V\) [11] and \(P_1 \approx 15\ kW\) focused to the spot \(0 \sim 60\mu\), coupling parameter is estimated as \(g \sim 1\mu^{-1} \).  

3. Embedded nonlinearity

The above described features allow to propose and to optimize the feasibility of independently engineering the NI and the resonantly enhanced higher-order \(\chi^{(3)}\) NLO response of a composite metamaterial with embedded NLO centers [ions or molecules] [Fig. 2(a) and (b)]. The sample is illuminated by two control fields, \(E_3\) and \(E_4\), so that the amplification of the NI signal, \(E_1\), and the generation of the counter-propagating PI idler, \(E_2\), [Fig. 2(c)] occur due to the FWM process \(\omega_1 + \omega_2 = \omega_3 + \omega_4\). The transmission factor for the signal, \(T_1(z = 0)\) is still described by Eq. (1), where \(g^2 = g_0^2 g_1\), \(g_0 = \sqrt{|k_1 k_2/\epsilon_1 \epsilon_2| 2\pi/\lambda} E_2 E_4\), and \(\Delta k = k_3 - k_4 - k_2 - k_1\) [13,17]. The schemes in Figs. 2(a) and (b) provide for opposite contributions to the NLO, absorption and refractive indices at \(\omega_1\) and \(\omega_2\). Hence, according to Figs. 1(b)–(f), the transmission properties for the signal are expected different. All local parameters become strongly dependent on the intensity of the control fields [31] and can be tailored by means of quantum control.

The results of numerical simulations for the example of the scheme in Fig. 2(a) and fully resonant control fields are shown in Fig. 3. Linear and NLO local parameters attributed to the embedded centers are calculated by the density-matrix method.
The rates properties of the model are as follows: energy level relaxation $G_1, G_2, G_3, G_4$ (where $G_i$ are the energy flux, wavevector and frequency for the backward-wave signal; $G_{s,k}, G_{o,k}$ and $G_0$ — the ordinary signal, idler and ordinary control fields, respectively). Resonance offsets for the signal and the idler are denoted as $G_{s,k}, G_{o,k}$.

The strength of the control fields is attributed to the host slab at the frequencies of the signal and the idler, is taken as $G_{s,k} = G_{o,k} = G_{0} = G_{ml}$. The quantity $G_{ml}$ denotes the value of absorption at $\omega_{ml} = \omega_{ML}$ introduced by the embedded centers with all driving fields turned off. The absorption, attributed to the host slab at the frequencies of the signal and the idler, is taken as $G_{s,k} = 2.3$ and $G_{o,k} = 2.1$. Relaxation properties of the model are as follows: energy level relaxation rates $\Gamma_s = 20, \Gamma_L = \Gamma_m = 120$; partial transition probabilities $\gamma_{sn} = 50, \gamma_{mn} = 90$ (all in $10^3$ s$^{-1}$); homogeneous transition half-widths $\Gamma_{sn} = 1, \Gamma_{nm} = 1.9, \Gamma_{ms} = 1.5, \Gamma_{mn} = 1.8$ (all in $10^3$ s$^{-1}$); $\Gamma_{gn} = 50, \Gamma_{ln} = 5$ (all in $10^3$ s$^{-1}$); $\lambda_1 = 756$ nm and $\lambda_2 = 480$ nm. For the given fields, the ratios of the energy level populations occur $r_1 = 0.42$, $r_2 = 0.19$, $r_n = 0.2$, $r_m = 0.19$ and, hence, no population-inversion or Raman-type gain is involved in the coupling. In conclusion, we have numerically demonstrated the feasibility of the all-optical manipulation of optical properties of NIMs through coherent nonlinear-optical energy transfer from the control to the signal field. The strong nonlinear optical response of the composite can be provided by either the nonlinearity of the building blocks of the negative-index host or by the embedded resonant four-level nonlinear centers. In the latter case, they can be adjusted independently. In addition, we have shown the opportunity for quantum control of the local optical parameters, which employs constructive and destructive quantum interference tailored by two auxiliary driving control fields. Such a possibility is proven with the aid of a realistic numerical model. The investigated features are promising for the compensation of losses in strongly absorbing NIMs, which is the key problem that limits numerous revolutionary applications of this novel class of electromagnetic materials. Among the other possible applications are a novel class of the miniature...
frequency-tunable narrow-band filters, quantum switchers, amplifiers and cavity-free microscopic optical parametric oscillators that allow the generation of entangled counter-propagating left- and right-handed photons. The unique features of the proposed photonic devices are revealed, such as the strongly resonant behavior with respect to the material thickness, the density of the embedded resonant centers and the intensities of the control fields, the feasibility of negating the linear phase-mismatch introduced by the host material, and the role of absorption or, conversely, the supplementary nonparametric amplification of the idler.
