The BL Lacertae object 3C 66A was detected in a flaring state by the Fermi Large Area Telescope (LAT) and VERITAS in 2008 October. In addition to these gamma-ray observations, F-GAMMA, GASP-WEBT, PAIRITEL, Swift, Chandra, and VERITAS in 2008 October. In addition to these gamma-ray observations, F-GAMMA, GASP-WEBT, PAIRITEL, Swift, Chandra, and Fermi-LAT gamma-ray band. The resulting spectral energy distribution can be well fitted using standard leptonic models with and without an external radiation field for inverse Compton scattering. It is found, however, that only the model with an external radiation field can accommodate the intra-night variability observed at optical wavelengths.

**Key words**: BL Lacertae objects: individual (3C 66A) – galaxies: active – gamma rays: galaxies

1. INTRODUCTION

The radio source 3C 66 (Bennett 1962) was shown by Mackay (1971) and Northover (1973) to actually consist of two unrelated radio sources separated by 0:11: a compact source (3C 66A) and a resolved galaxy (3C 66B). 3C 66A was subsequently identified as a quasi-stellar object by Wills & Wills (1974), and as a BL Lacertae object by Smith et al. (1976) based on its optical spectrum. 3C 66A is now a well-known blazar which, like other active galactic nuclei (AGNs), is thought to be powered by accretion of material onto a supermassive black hole located in the central region of the host galaxy (Urry & Padovani 1995). Some AGNs present strong relativistic outflows in the form of jets, where particles are believed to be accelerated to ultra-relativistic energies and gamma rays are subsequently produced. Blazars are the particular subset of AGNs with jets aligned to the observer’s line of sight. Indeed, the jet of 3C 66A has been imaged using very long baseline interferometry (VLBI; Taylor et al. 1996; Jorstad et al. 2001; Marscher et al. 2002; Britzen et al. 2007) and superluminal motion has been inferred (Jorstad et al. 2001; Britzen et al. 2008). This is indicative of the relativistic Lorentz factor of the jet and its small angle with respect to the line of sight.

BL Lacs are known for having very weak (if any) detectable emission lines, which makes determination of their redshift quite difficult. The redshift of 3C 66A was reported as $z = 0.444$ by Miller et al. (1978) and also (although tentatively) by Kinney et al. (1991). Each measurement, however, is based on the
measurement of a single line and is not reliable (Bramel et al. 2005). Recent efforts (described in Section 2.5) to provide further constraints have proven unsuccessful.

Similar to other blazars, the spectral energy distribution (SED) of 3C 66A has two pronounced peaks, which suggests that at least two different physical emission processes are at work (e.g., Joshi & Böttcher 2007). The first peak, extending from radio to soft X-ray frequencies, is likely due to synchrotron emission from high-energy electrons, while different emission models have been proposed to explain the second peak, which extends up to gamma-ray energies. Given the location of its synchrotron peak ($\lesssim 10^{15}$ Hz), 3C 66A is further sub-classified as an intermediate synchrotron peaked (ISP) blazar (Abdo et al. 2010c).

The models that have been proposed to explain gamma-ray emission in blazars can be roughly categorized into leptonic or hadronic, depending on whether the accelerated particles responsible for the gamma-ray emission are primarily electrons and positrons (hereafter “electrons”) or protons. In leptonic models, high-energy electrons produce gamma rays via inverse Compton (IC) scattering of low-energy photons. In synchrotron self-Compton (SSC) models, the same population of electrons responsible for the observed gamma rays generates the low-energy photon field through synchrotron emission. In external Compton (EC) models, the low-energy photons originate outside the emission volume of the gamma rays. Possible sources of target photons include accretion-disk photons radiated directly into the jet (Dermer & Schlickeiser 1993), accretion-disk photons scattered by emission-line clouds or dust into the jet (Sikora et al. 1994), synchrotron radiation re-scattered back into the jet by broad-line emission clouds (Ghisellini & Madau 1996), jet emission from an outer slow jet sheet (Ghisellini et al. 2005), or emission from faster or slower portions of the jet (Georganopoulos & Kazanas 2004). In hadronic models, gamma rays are produced by high-energy protons, either via proton synchrotron radiation (Mücke et al. 2003), or via secondary emission from photo-pion and photo-pair-production reactions (see Böttcher (2007) and references therein for a review of blazar gamma-ray emission processes).

One of the main obstacles in the broadband study of gamma-ray blazars is the lack of simultaneity, or at least contemporaneousness, of the data at the various wavelengths. At high energies, the situation is made even more difficult due to the lack of objects that can be detected by MeV/GeV and TeV observatories on comparable timescales. Indeed, until recently the knowledge of blazars at gamma-ray energies had been obtained from observations performed in two disjoint energy regimes: (1) the high-energy range (20 MeV $< E < 10$ GeV) studied in the 1990s by EGRET (Thompson et al. 1993) and (2) the very high energy (VHE) regime ($E > 100$ GeV) observed by ground-based instruments such as imaging atmospheric Cherenkov telescopes (IACTs; Weekes 2000). Only Markarian 421 was detected by both EGRET and the first IACTs (Kerrick et al. 1995). Furthermore, blazars detected by EGRET at MeV/GeV energies are predominantly flat-spectrum radio quasars (FSRQs), while TeV blazars are, to date, predominantly BL Lacs. It is important to understand these observational differences since they are likely related to the physics of the AGN (Cavaliere & D’Elia 2002) or to the evolution of blazars over cosmic time (Böttcher & Dermer 2002).

The current generation of gamma-ray instruments (AGILE, Fermi, H.E.S.S., MAGIC, and VERITAS) is closing the gap between the two energy regimes due to improved instrument sensitivities, leading us toward a deeper and more complete characterization of blazars as high-energy sources and as a population (Abdo et al. 2009b). An example of the successful synergy of space-borne and ground-based observatories is provided by the joint observations of 3C 66A by the Fermi LAT and the Very Energetic Radiation Imaging Telescope Array System (VERITAS) during its strong flare of 2008 October. The flare was originally reported by VERITAS (Swordy 2008; Acciari et al. 2009) and soon after contemporaneous variability was also detected at optical to infrared wavelengths (Larionov et al. 2008) and in the Fermi-LAT energy band (Tosti 2008). Follow-up observations were obtained at radio, optical, and X-ray wavelengths in order to measure the flux and spectral variability of the source across the electromagnetic spectrum and to obtain a quasi-simultaneous SED. This paper reports the results of this campaign, including the broadband spectrum and a model interpretation of this constraining SED.

2. OBSERVATIONS AND DATA ANALYSIS

2.1. VERITAS

VERITAS is an array of four 12 m diameter imaging Cherenkov telescopes in southern Arizona, USA (Acciari et al. 2008b). 3C 66A was observed with VERITAS for 14 hr from 2007 September through 2008 January and for 46 hr between 2008 September and 2008 November. These observations (hereafter 2007 and 2008 data) add up to $\sim 32.8$ hr of live time after data quality selection. The data were analyzed following the procedure described in Acciari et al. (2008b).

As reported in Acciari et al. (2009), the average spectrum measured by VERITAS is very soft, yielding a photon index $\Gamma$ of $4.1 \pm 0.4_{\text{stat}} \pm 0.6_{\text{sys}}$ when fitted to a power law $dN/dE \propto E^{-\Gamma}$. The average integral flux above 200 GeV measured by VERITAS is $(1.3 \pm 0.1) \times 10^{-11}$ cm$^{-2}$ s$^{-1}$, which corresponds to 6% of the Crab Nebula’s flux above this threshold. In addition, a strong flare with night-by-night VHE-flux variability was detected in 2008 October. For this analysis, the VERITAS spectrum is calculated for the short time interval 2008 October 8–10 (MJD 54747–54749; hereafter flare period), and for a longer period corresponding to the dark run$^{124}$ where most of the VHE emission from 3C 66A was detected (MJD 54734–54749). It should be noted that the flare and dark run intervals overlap and are therefore not independent. Table 1 lists the relevant information from each data set.

As shown in Figure 1, the flare and dark run spectra are very soft, yielding nearly identical photon indices of $4.1 \pm 0.6_{\text{stat}} \pm 0.6_{\text{sys}}$, entirely consistent with that derived from the full 2007 and 2008 data set. The integral flux above 200 GeV for the flare period is $(2.5 \pm 0.4) \times 10^{-11}$ cm$^{-2}$ s$^{-1}$, while the average flux for the dark run period is $(1.4 \pm 0.2) \times 10^{-11}$ cm$^{-2}$ s$^{-1}$. The extragalactic background light (EBL) de-absorbed spectral points for the dark run calculated using the optical depth values of Franceschini et al. (2008) and assuming a nominal redshift of $z = 0.444$ are also shown in Figure 1. These points are well fitted by a power-law function with $\Gamma = 1.9 \pm 0.5$.

---

$^{124}$ IACTs like VERITAS do not operate on nights with bright moonlight. The series of nights between consecutive bright moonlight periods is usually referred to as a dark run.
The LAT on board the Fermi Gamma-ray Space Telescope is a pair-conversion detector sensitive to gamma rays with energies between 20 MeV and several hundred GeV (Atwood et al. 2009). Since launch the instrument has operated almost exclusively in sky survey mode, covering the whole sky every 3 hr. The overall coverage of the sky is fairly uniform, with exposure variations of \(\leq 15\%\) around the mean value. The LAT data are analyzed using ScienceTools v9r15p5 and instrument response functions P6V3 (available via the Fermi science support center125). Only photons in the diffuse event class are selected for this analysis because of their reduced charged-particle background contamination and very good angular reconstruction. A zenith angle \(<105^{\circ}\) cut in instrument coordinates is used to avoid gamma rays from the Earth limb. The diffuse emission from the Galaxy is modeled using a spatial model (\textit{gll\_iem\_v02.fit}) which was refined with Fermi-LAT data taken during the first year of operation. The extragalactic diffuse and residual instrumental backgrounds are modeled as an isotropic component and are included in the fit.126 The data are analyzed with an unbinned maximum likelihood technique (Mattox et al. 1996) using the likelihood analysis software developed by the LAT team.

Although 3C 66A was detected by EGRET as source 3EG J0222+4253 (Hartman et al. 1999), detailed spatial and timing analyses by Kuiper et al. (2000) showed that this EGRET source actually consists of the superposition of 3C 66A and the nearby millisecond pulsar PSR J0218+4232 which is \(0.96^{\circ}\) distant from the blazar. This interpretation of the EGRET data is verified by Fermi-LAT, whose improved angular resolution permits the clear separation of the two sources as shown in Figure 2. Furthermore, the known pulsar period is detected with high confidence in the Fermi-LAT data (Abdo et al. 2009a). More importantly for this analysis, the clear separation between the pulsar and the blazar enables studies of each source independently in the maximum likelihood analysis, and thus permits an accurate determination of the spectrum and localization of each source, with negligible contamination.

Figure 2 also shows the localization of the Fermi and VERITAS sources with respect to blazar 3C 66A and radio galaxy 3C 66B (see caption in Figure 2 for details). It is clear from the map that the Fermi-LAT and VERITAS localizations are consistent and that the gamma-ray emission is confidently associated with the blazar and not with the radio galaxy. Some small contribution in the Fermi-LAT data from radio galaxy 3C 66B as suggested by Aliu et al. (2009) and Tavecchio & Ghisellini (2009) cannot be excluded, given the large spillover of low-energy photons from 3C 66A at the location of 3C 66B. This is due to the long tails of the Fermi-LAT point-spread function at low energies as described in Atwood et al. (2009). Nevertheless, considering only photons with energy \(E > 1\,\text{GeV}\), the upper limit (95\% confidence level) for a source at the location of 3C 66B is \(2.9 \times 10^{-8}\,\text{cm}^{-2}\,\text{s}^{-1}\) for the dark run period (with a test statistic127 (TS) = 1.3). For the 11 months of data corresponding to the first Fermi-LAT catalog (Abdo et al. 2010a), the upper limit is \(4.9 \times 10^{-9}\,\text{cm}^{-2}\,\text{s}^{-1}\) (TS = 5.8).

As in the analysis of the VERITAS observations, the Fermi-LAT spectrum is calculated for the flare and for the dark run periods. The Fermi flare period flux \(F(E > 100\,\text{MeV}) = (5.0 \pm 1.4_{\text{stat}} \pm 0.3_{\text{sys}}) \times 10^{-7}\,\text{cm}^{-2}\,\text{s}^{-1}\) is consistent with errors with the dark run flux of \((3.9 \pm 0.5_{\text{stat}} \pm 0.3_{\text{sys}}) \times 10^{-7}\,\text{cm}^{-2}\,\text{s}^{-1}\). In both cases, the Fermi-LAT spectrum is quite hard and can be described by a power law with a photon index \(\Gamma = 1.8 \pm 0.1_{\text{stat}} \pm 0.1_{\text{sys}}\) and \(1.9 \pm 0.1_{\text{stat}} \pm 0.1_{\text{sys}}\) in the flare period and dark run intervals, respectively. Both spectra are shown in the high-energy SED in Figure 1.

2.3. Chandra

3C 66A was observed by the Chandra observatory on 2008 October 6 for a total of 37.6 ks with the Advanced CCD Imaging Spectrometer (ACIS), covering the energy band between 0.3 and 10 keV. The source was observed in the continuous clocking mode to avoid pile-up effects. Standard analysis tools (CIAO 4.1) and calibration files (CALDB v3.5.0) provided by the Chandra X-ray center128 are used.

The time-averaged spectrum is obtained and rebinned to ensure that each spectral channel contains at least 25 background-subtracted counts. This condition allows the use of the \(\chi^2\).

---

126 http://fermi.gsfc.nasa.gov/ssc/data/access/lat/BackgroundModels.html.
127 The test statistic (TS) value quantifies the probability of having a point source at the location specified. It is roughly the square of the significance value: a TS of 25 corresponds to a signal of approximately 5 standard deviations (Abdo et al. 2010a).

Notes. Live time corresponds to the effective exposure time after accounting for data quality selection. \(N_{\text{on}}\) (\(N_{\text{off}}\)) corresponds to the number of on (off)-source events passing background-rejection cuts. Alpha is the normalization of off-source events and the excess is equal to \(N_{\text{on}} - \alpha N_{\text{off}}\). The significance is expressed in number of standard deviations and is calculated according to Equation (17) of Li & Ma (1983). See Acciari et al. (2009) for a complete description of the VERITAS analysis.
Figure 2. Smoothed count map of the 3C 66A region as seen by Fermi-LAT between 2008 September 1 and December 31 with $E > 100$ MeV. The color bar has units of counts per pixel and the pixel dimensions are $0.1 \times 0.1$. The contour levels have been smoothed and correspond to 2.8, 5.2, and 7.6 counts per pixel. The locations of 3C 66A and 3C 66B (a radio galaxy that is 0.11 away) are shown as a cross and as a diamond, respectively. The location of millisecond pulsar PSR 0218+4232 is also indicated with a white cross. The magenta circle represents the VERITAS localization of the VHE source (RA; DEC) = $(2h22m41.6s6\pm1.6s7\pm6.6s0\pm60_\text{sys})$ as reported in Acciari et al. (2009). The blue interior circle represents the 95% error radius of the Fermi-LAT localization (RA; DEC) = $(02h22m40.3s3\pm4.5s5; 43^\circ02'18.6\pm42'1)$ as reported in the Fermi-LAT first source catalog (Abdo et al. 2010a). All positions are based on the J2000 epoch.

quality-of-fit estimator to find the best-fit model. XSPEC v12.4 (Arnaud 1996) is used for the spectral analysis and fitting procedure. Two spectral models have been used to fit the data: single power law and broken power law. Each model includes galactic H\text{I} column density ($N_{\text{H,gal}} = 8.99 \times 10^{20}$ cm$^{-2}$) according to Dickey & Lockman (1990), where the photoelectric absorption is set with the XSPEC model \textit{phabs}.\textsuperscript{129} An additional local H\text{I} column density was also tried but in both cases the spectra were consistent with pure galactic density. Consequently, the column density has been fixed to the galactic value in each model, and the results obtained are presented in Table 2. An $F$-test was performed to demonstrate that the spectral fit improves significantly when using the extra degrees of freedom of the broken power-law model. Table 2 also contains the results of the $F$-test.

2.4. Swift XRT and UVOT

Following the VERITAS detection of VHE emission from 3C 66A, Target of Opportunity (ToO) observations of 3C 66A with Swift were obtained for a total duration of $\sim 10$ ks. The Swift satellite observatory comprises an UV–Optical telescope (UVOT), an X-ray telescope (XRT), and a Burst Alert Telescope (Gehrels et al. 2004). Data reduction and calibration of the XRT data are performed with HEASoft v6.5 standard tools. All XRT data presented here are taken in photon counting mode with negligible pile-up effects. The X-ray spectrum of each observation is fitted with an absorbed power law using a fixed Galactic column density from Dickey & Lockman (1990), which gives good $\chi^2$ values for all observations. The measured photon spectral index ranges between 2.5 and 2.9 with a typical statistical uncertainty of 0.1.

UVOT obtained data through each of six color filters, $V$, $B$, and $U$ together with filters defining three ultraviolet passbands $UVW1$, $UVM2$, and $UVW2$ with central wavelengths of 260 nm, 220 nm, and 193 nm, respectively. The data are calibrated using standard techniques (Poole et al. 2008) and corrected for Galactic extinction by interpolating the absorption values from Schlegel et al. (1998) ($E_{B-V} = 0.083$ mag) with the galactic spectral extinction model of Fitzpatrick (1999).

2.5. Optical to Infrared Observations

The $R$ magnitude of the host galaxy of 3C 66A is $\sim 19$ in the optical band (Wurtz et al. 1996). Its contribution is negligible compared to the typical AGN magnitude of $R \lesssim 15$; therefore, host-galaxy correction is not necessary.

GASP-WEBT. 3C 66A is continuously monitored by telescopes affiliated to the GLAST-AGILE support program of the Whole Earth Blazar Telescope (GASP-WEBT; see Villata et al.
Abdo et al.

Figure 3. 3C 66A light curves covering 2008 August 22 to December 31 in order of increasing wavelength. The VERITAS observations are combined to obtain nightly flux values and the dashed and dotted lines represent the average flux measured from the 2007 and 2008 data and its standard deviation. The Fermi-LAT light curves contain time bins with a width of 3 days. The average flux and average photon index measured by Fermi-LAT during the first six months of science operations are shown as horizontal lines in the respective panels. In all cases, the Fermi-LAT photon index is calculated over the 100 MeV to 200 GeV energy range. The long-term light curves at optical and infrared wavelengths are presented in the two bottom panels. In the bottom panel, GASP-WEBT and PAIRITEL observations are represented by open and solid symbols, respectively.

Figure 4. 3C 66A light curves covering the period centered on the gamma-ray flare (2008 October 1–10). The VERITAS and Fermi-LAT panels were already described in the caption of Figure 3. Swift Target-of-Opportunity (ToO) observations (panels 3–5 from the top) were obtained following the discovery of VHE emission by VERITAS (Swordy 2008). Swift-UVOT and MDM observations are represented by open and solid symbols, respectively. The optical light curve in panel 6 from the top displays intra-night variability. An example is identified in the plot, when a rapid decline of the optical flux by $\Delta F/\Delta t \sim -0.2$ mJy hr$^{-1}$ is observed on MJD 54747.

in Namibia, which monitors this source periodically. Twenty photometric observations are available starting on MJD 54740 and are shown in Figures 3 and 4.

PAIRITEL. Near-infrared observations in the $J$, $H$, and $K_s$ were obtained following the VHE flare with the 1.3 m Peters Automated Infrared Imaging Telescope (PAIRITEL; see Bloom et al. 2006) located at the Fred Lawrence Whipple Observatory. The resulting light curves using differential photometry with four nearby calibration stars are shown in Figure 4.

Keck. The optical spectrum of 3C 66A was measured with the LRIS spectrometer (Oke et al. 1995) on the Keck I telescope on the night of 2009 September 17 under good conditions. The instrument configuration resulted in a full width half-maximum of $\sim 250$ km s$^{-1}$ over the wavelength range 3200–5500 Å (blue side) and $\sim 200$ km s$^{-1}$ over the range 6350–9000 Å (red side). A series of exposures totaling 110 s (blue) and 50 s (red) were obtained, yielding a signal-to-noise (S/N) per resolution element of $\sim 250$ and 230 for the blue and red cameras, respectively. The data were reduced with the LowRedux$^{30}$ pipeline and calibrated using a spectrophotometric star observed on the same night.

$^{30}$ http://www.ucolick.org/~xavier/LowRedux/index.html.
Inspection of the 3C 66A spectrum reveals no spectral features aside from those imposed by Earth’s atmosphere and the Milky Way (Ca H+K). Therefore, these new data do not offer any insight on the redshift of 3C 66A and in particular are unable to confirm the previously reported value of $z = 0.444$ (Miller et al. 1978).

2.6. Radio Observations

Radio observations are available thanks to the F-GAMMA (Fermi-Gamma-ray Space Telescope AGN Multi-frequency Monitoring Alliance) program, which is dedicated to monthly monitoring of selected Fermi-LAT blazars (Fuhrmann et al. 2007; Angelakis et al. 2008). Radio flux density measurements were conducted with the 100 m Effelsberg radio telescope at 4.85, 8.35, 10.45, and 14.60 GHz on 2008 October 16. These data are supplemented with an additional measurement at 86 GHz conducted with the IRAM 30 m telescope (Pico Veleta, Spain) on 2008 October 8. The data were reduced using standard procedures described in Fuhrmann et al. (2008). Additional radio observations taken between 2008 October 5 and 15 (contemporaneous to the flare period) are provided by the Medicina, Metsahovi, Noto, and UMRAO observatories, all of which are members of the GASP-WEBT consortium.
3. DISCUSSION

3.1. Light Curves

The resulting multi-wavelength light curves from this campaign are shown in Figure 3 for those bands with long-term coverage and in Figure 4 for those observations that were obtained shortly before and after the gamma-ray flare. The VERITAS observations are combined to obtain nightly ($E > 200 \text{ GeV}$) flux values since no evidence for intra-night variability is observed. The highest flux occurred on MJD 54749 and significant variability is observed during the whole interval ($\chi^2$ probability less than $10^{-4}$ for a fit of a constant flux).

The temporal dependence of the Fermi-LAT photon index and integral flux above 100 MeV and 1 GeV are shown with time bins of width 3 days in Figure 3. For those time intervals with no significant detection, a 95% confidence flux upper limit is calculated. The flux and photon index from the Fermi-LAT first source catalog (Abdo et al. 2010a) are shown as horizontal lines for comparison. These values correspond to the average flux and photon index measured during the first 11 months of Fermi operations, and thus span the time interval considered in the figures. It is evident from the plot that the VHE flare detected by VERITAS starting on MJD 54740 is coincident with a period of high flux in the Fermi energy band. The photon index during this time interval is consistent within errors with the average photon index $\Gamma = 1.95 \pm 0.03$ measured during the first six months of the Fermi mission (Abdo et al. 2010b).

Long-term and well-sampled light curves are available at optical and near-infrared wavelengths thanks to observations by GASP-WEBT, ATOM, MDM, and PAIRITEL. Unfortunately, radio observations were too limited to obtain a light curve and no statement about variability in this band can be made. The best sampling is available for the $R$ band, for which variations with a factor of $\geq 2$ are observed in the long-term light curve. Furthermore, variability on timescales of less than a day is observed, as indicated in Figure 4, and as previously reported by Böttcher et al. (2009) following the WEBT (Whole Earth Blazar Telescope) campaign on 3C 66A in 2007 and 2008.

The increase in gamma-ray flux observed in the Fermi band seems contemporaneous with a period of increased flux in the optical, and to test this hypothesis, the discrete correlation function (DCF) is used (Edelson & Krolik 1988). Figure 5 shows the DCF of the $F(E > 1 \text{ GeV})$ gamma-ray band with respect to the $R$ band with time-lag bins of 3, 5, and 7 days. The profile of the DCF is consistent for all time-lag bins, indicating that the result is independent of bin size. The DCF with time-lag bins of 3 days was fitted with a Gaussian function of the form $D(\tau)/F_{\text{esc}} \propto \exp(-\tau^2/\sigma^2).$ The fit to the 3-day bin size distribution is shown in the plot as a solid black line and the best-fit parameters are $C_{\text{max}} = 1.1 \pm 0.3$, $\tau_0 = (0.7 \pm 0.7)$ days, and $\sigma = (3.3 \pm 0.7)$ days.

with respect to the optical–GeV flare but given the coverage gaps no firm conclusion can be drawn (e.g., the flare could have been already underway when the observations took place). No such lag is expected from the homogeneous model described in the next section but could arise in models with complex energy stratification and geometry in the emitting region.

3.2. SED and Modeling

The broadband SED derived from these observations is presented in Figure 6 and modeled using the code of Böttcher & Chiang (2002). In this model, a power-law distribution of ultrarelativistic electrons and/or pairs with lower and upper energy cutoffs at $q_{\text{min}}$ and $q_{\text{max}}$, respectively, and power-law index $q$ is injected into a spherical region of comoving radius $R_0$. The injection rate is normalized to an injection luminosity $L_*$, which is a free input parameter of the model. The model assumes a temporary equilibrium between particle injection, radiative cooling due to synchrotron and Compton losses, and particle escape on a time-constant $\eta_{\text{esc}} \equiv \eta_{\text{esc}} R_0/c$, where $\eta_{\text{esc}}$ is a scale parameter in the range $\sim 250$–500. Both the internal synchrotron photon field (SSC) and external photon sources (EC) are considered as targets for Compton scattering. The emission region is moving with a bulk Lorentz factor $\Gamma$ along the jet. To reduce the number of free parameters, we assume that the jet is oriented with respect to the line of sight at the superluminal angle so that the Doppler factor is equal to $D = (\Gamma[1 - \beta \cos \theta_{\text{obs}}])^{-1} = \Gamma$, where $\theta_{\text{obs}}$ is the angle of the jet with respect to the line of sight. Given the uncertainty in the redshift determination of 3C 66A, a range of plausible redshifts, namely $z = 0.1, 0.2, 0.3$, and the generally used catalog value $z = 0.444$, are considered for the modeling. All model fits include EBL absorption using the optical depth values from Franceschini et al. (2008).

Most VHE blazars known to date are high synchrotron peaked (HSP) blazars, whose SEDs can often be fitted satisfactorily with pure SSC models. Since the transition from HSP to ISP is continuous, a pure SSC model was fitted first to the radio through VHE gamma-ray SED. Independently of the model under consideration, the low-frequency part of the SED ($< 10^{20}$ Hz) is well fitted with a synchrotron component, as shown in Figure 6.
For clarity, only the high-frequency range is shown in Figures 7 and 8, where the different models are compared. As can be seen from the figures, a reasonable agreement with the overall SED can be achieved for any redshift in the range explored. The weighted sum of squared residuals has been calculated for the Fermi-LAT and VERITAS flare data (8 data points in total) in order to quantify the scatter of the points with respect to the model and is shown in Table 4. The best agreement is achieved when the source is located at $z \sim 0.2$–0.3. For lower redshifts, the model spectrum is systematically too hard, while at $z = 0.444$ the model spectrum is invariably too soft as a result of EBL absorption. It should be noted that the EBL model of Franceschini et al. (2008) predicts some of the lowest optical depth values in comparison to other models (Finke et al. 2010; Gilmore et al. 2009; Stecker et al. 2006). Thus, a model spectrum with redshift of 0.3 or above would be even harder to reconcile with the observations when using other EBL models.

A major problem of the SSC models with $z \gtrsim 0.1$ is that $R_B$ is of the order of $5 \times 10^{16}$ cm. This does not allow for variability timescales shorter than $\lesssim 1$ day, which seems to be in contrast with the optical variability observed on shorter timescales. A smaller $R_B$ would require an increase in the electron energy density (with no change in the magnetic field in order to preserve the flux level of the synchrotron peak) and would lead to an internal gamma–gamma absorption. This problem could be mitigated by choosing extremely high Doppler factors, $D \gtrsim 100$. However, these are significantly larger than the values inferred from VLBI observations of Fermi-LAT blazars (Savolainen et al. 2010). Moreover, all SSC models require very low magnetic fields, far below the value expected from equipartition ($\epsilon_B = L_B/L_e \sim 10^{-3} \ll 1$), where $L_B$ is the Poynting flux derived from the magnetic energy density and $L_e$ is the energy flux of the electrons propagating along the jet. Table 4 lists the parameters used for the SSC models displayed in Figure 7.

Subsequently, an external infrared radiation field with ad hoc properties was included as a source of photons to be Compton scattered. For all SSC+EC models shown in Figure 8, the peak frequency of the external radiation field is set to $\nu_{\text{ext}} = 1.4 \times 10^{14}$ Hz, corresponding to near-IR. This adopted value is high enough to produce $E \gtrsim 100$ GeV photons from IC scattering off the synchrotron electrons and at the same time is below the energy regime in which Klein–Nishina effects take place. Although the weighted sums of squared residuals for EC+SSC models are generally worse than for pure SSC models, reasonable agreement with the overall SED can still be achieved for redshifts $z \lesssim 0.3$. Furthermore, all SSC+EC models are consistent with a variability timescale of $\Delta t_{\text{var}} \sim 4$ hr. This is in better agreement with the observed variability at optical wavelengths than the pure SSC interpretation. Also, while the SSC+EC interpretation still requires sub-equipartition magnetic fields, the magnetic fields are significantly closer to equipartition than in the pure SSC case, with $L_B/L_e \sim 0.1$. The parameters of the SSC+EC models are listed in Table 5.

Models with and without EC component yield the best agreement with the SED if the source is located at a redshift $z \sim 0.2$–0.3. Of course, this depends on the EBL model used in the analysis. An EBL model that predicts higher attenuation than Franceschini et al. (2008) would lead to a lower redshift range and make it even more difficult to have agreement between the SED models and the data when the source is located at redshifts $z \gtrsim 0.4$. Finally, it is worth mentioning that the redshift range $z \sim 0.2$–0.3 is in agreement with previous estimates by Finke et al. (2008), who estimate the redshift of 3C 66A to be $z = 0.321$ based on the magnitude of the host galaxy, and by Prandini et al. (2010) who use an empirical relation between the previously reported Fermi-LAT and IACTs spectral slopes of blazars and their redshifts to estimate the redshift of 3C 66A to be below $z = 0.34 \pm 0.05$. 

---

Figure 6. Broadband SED of 3C 66A during the 2008 October multi-wavelength campaign. The observation that corresponds to each set of data points is indicated in the legend. As an example, the EBL-absorbed EC+SSC model for $z = 0.3$ is plotted here for reference. A description of the model is provided in the text.
A detailed study of hadronic versus leptonic modeling of the 2008 October data will be published elsewhere, but it is worth mentioning that the synchrotron proton blazar (SPB) model has been used to adequately reproduce the quasi-simultaneous SED observed during the 2003–2004 multi-wavelength campaign (Reimer et al. 2008). On that occasion rapid intra-day variations down to a 2 hr timescale were observed, while during the 2008 campaign presented here these variations seem less rapid. Qualitatively, the longer timescale variations may be due to a lower Doppler beaming at the same time that a strongly reprocessed proton synchrotron component dominates the high energy output of this source.

4. SUMMARY

Multi-wavelength observations of 3C 66A were carried out prompted by the gamma-ray outburst detected by the VERITAS and Fermi observatories in 2008 October. This marks the first occasion that a gamma-ray flare is detected by GeV and TeV instruments in comparable timescales. The light curves obtained show strong variability at every observed wavelength and, in particular, the flux increase observed by VERITAS and Fermi is coincident with an optical outburst. The clear correlation between the Fermi-LAT and R optical light curves permits one to go beyond the source association reported in the first Fermi-LAT source catalog (Abdo et al. 2010a) and finally identify the gamma-ray source 1FGL J0222.6+4302 as blazar 3C 66A.

For the modeling of the overall SED, a reasonable agreement can be achieved using both a pure SSC model and an SSC+EC model with an external near-infrared radiation field as an additional source for Compton scattering. However, the pure SSC model requires (1) a large emission region, which is inconsistent with the observed intra-night scale variability at optical wavelengths, and (2) low magnetic fields, about a factor $\sim 10^{-3}$ below equipartition. In contrast, an SSC+EC interpretation allows for variability on timescales of a few hours.
Figure 8. EC+SSC model for redshifts \( z = 0.444, 0.3, 0.2, \) and 0.1 from top to bottom. The individual EBL-absorbed EC and SSC components are indicated as dash-dotted and dotted lines, respectively. The sum is shown as a solid red line (dashed when de-absorbed). The best agreement between the model and the data is achieved when the source is located at \( z \sim 0.2 \).

Notes. All SSC models require very low magnetic fields, far below the value expected from equipartition (i.e., \( \epsilon_B \ll 1 \)). The weighted sum of squared residuals to the VERITAS and Fermi-LAT data and the total value for the combined data set are included at the bottom of the table. The best agreement between the model and the data is obtained when the source is at redshift \( z = 0.2-0.3 \).
and for magnetic fields within about an order of magnitude of, though still below, equipartition. It is worth noting that the results presented here agree with the findings following the (E > 200 GeV) flare of blazar W Comae (also an ISP) in 2008 March (Acciari et al. 2008a). In both cases, the high optical luminosity is expected to play a key role in providing the seed population for IC scattering.

Intermediate synchrotron peaked blazars like 3C 66A are well suited for simultaneous observations by Fermi-LAT and ground-based IACTs like VERITAS. Relative to the sensitivities of these instruments, ISPs are bright enough to allow for time-resolved spectral measurements in each band during flaring episodes. These types of observations coupled with extensive multi-wavelength coverage at lower energies will continue to provide key tests of blazar emission models.

The Fermi-LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique/Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden. Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France.

The VERITAS collaboration acknowledges the generous support from the US Department of Energy, the US National Science Foundation, and the Smithsonian Institution, by NSERC in Canada, by Science Foundation Ireland, and by STFC in UK. The VERITAS collaboration also acknowledges the excellent work of the technical support staff at the FLWO and the collaborating institutions in the construction and operation of the instrument, as well as support from the NASA/Swift guest investigator program (grant NNX08AU13G) for the Swift observations.

PAIRITEL is operated by the Smithsonian Astrophysical Observatory (SAO) and was made possible by a grant from the Harvard University Milton Fund, a camera loan from the University of Virginia, and continued support of the SAO and UC Berkeley. The PAIRITEL project is further supported by NASA/Swift Guest Investigator grant NNG06GH50G. This research is partly based on observations with the 100 m telescope of the MPIfR (Max-Planck-Institut für Radioastronomie) at Effelsberg and has also made use of observations with the IRAM 30 m telescope. The Metsähovi team acknowledges the support from the Academy of Finland. The Abastumani Observatory team acknowledges financial support by the Georgian National Science Foundation and the Ministry of Education and Science of Georgia (Marise) and the Swedish National Space Board in Sweden. Additional support for the VERITAS simulations used in this work have been performed on the joint Fermilab-KICP supercomputing cluster, supported by grants from Fermilab, the Kavli Institute for Cosmological Physics, and the University of Chicago.
