ABSTRACT

In this paper, an experimental study is presented on the influence of PET wrapping on shear performance, such as diagonal shear cracking load, peak load, and energy dissipation of RC columns with stirrup corrosion before strengthening. The experimental program involved an electrochemical process to accelerate the migration of chlorides from an external electrolyte into the tested columns, a wetting–drying cycle process with a controlled current to speed up the corrosion of the stirrup in the tested columns, the strengthening of corroded columns with PET wrapping, and a pseudostatic test to determine the shear capacity of the tested beams. The shear performance of PET wrapped RC columns with different corrosion levels in stirrups, including the diagonal cracking strength, the peak strength, the ductility ratio, and the energy dissipation ability, was examined and compared.

Keywords: corrosion, strengthening, shear, energy dissipation, column

1. INTRODUCTION

Large hoop spacing and lack of stirrup anchorage at the plastic hinge locations of columns may lead to spalling of cover concrete and buckling of column longitudinal bars in concrete columns under the effect of earthquake-induced reversed moments. Meanwhile, reinforcement corrosion has been observed to a great extent, especially in the marine environment. Past experiences have shown that reinforcement corrosion reduces the beam and column capacity due to steel area losses, bond deterioration, reduction in the effective concrete area, etc. (Li & Li, 2014; Ma, Che, & Gong, 2012; Pantazopoulou, Bonacci, Sheikh, Thomas, & Hearn, 2001). Despite a large body of literature on the influence of reinforcing steel corrosion on the flexural capacity of RC columns, there are few works that have dealt with the reduction in shear capacity of RC columns due to the corrosion of stirrups (Xia, Jin, & Li, 2011). Actually, stirrups would be first attacked by chlorides in a chloride environment since they are nearer to the concrete surface than the longitudinal steel bars.

Extensive investigations on the seismic retrofitting of reinforced concrete (RC) columns have been undertaken in recent years. There has been an enormous interest in the research and application of fiber reinforced polymers (FRPs) in RC column seismic retrofitting since the 1980s. The basic concepts and relatively recent survey in the use of FRPs for strengthening of concrete structures are covered in a review article by Triantafyllou (2001). Many researchers have proven

the effectiveness of applications of conventional FRP materials, such as aramid, carbon, and glass, in shear and ductility enhancement (Bakis et al., 2002; Benzaid, Chikh, & Mesbah, 2008; Teng, Chen, Smith, & Lam, 2003; Wu et al., 2006). However, due to low fracturing strain capacity of conventional FRPs [around 1.5% for carbon FRP (CFRP), 2% for glass FRP (GFRP), and 3% for aramid FRP (AFRP)], the fiber materials tend to fail sooner due to fiber breakage, which causes a loss of confinement and hence the load-carrying capacity as well as the ductility potential. New fiber materials, such as polyacetal fiber (PAF), polyethylene naphthalate (PEN), and polyethylene terephthalate (PET), have properties of large fracturing strain and low stiffness in comparison to aramid, carbon, and glass fibers (Jirawattanasomkul, Dai, Zhang, Senda, & Ueda, 2013). Previous studies (Anggawidjaja, Ueda, Dai, & Nakai, 2006; Dai, Bai, & Teng, 2011; Dai, Lam, & Ueda, 2012) proved that concrete or RC members wrapped by PET and PEN fiber sheets with large fracturing strain could efficiently enhance the ductility of concrete or RC members, regardless of their low stiffness. However, the effect of steel corrosion on the efficiency of FRP wrapping to enhance the member behavior and the corresponding remains unclear.

In this paper, an experimental study is presented on the influence of PET wrapping on shear strength, ductility, and energy absorptivity of RC columns with stirrup corrosion before strengthening. The experimental program involved an electrochemical process to accelerate the migration of chlorides from an external

electrolyte into the tested columns, a wetting–drying cycle process with a controlled current to speed up the corrosion of the stirrup in the tested columns, the strengthening of corroded columns with PET warping, and a pseudostatic test to determine the shear capacity of the tested beams. The shear performance of PET wrapped RC columns with different corrosion levels in stirrups was examined.

2. EXPERIMENTAL PROGRAM

2.1 Details of test setup

A total of 11 RC rectangular columns with footings were constructed, which consisted of four un-strengthened control specimens with different levels of stirrup corrosion (designed to be 0%, 10%, 15%, and 25%) and seven strengthened specimens with different layers of PET fiber warping (one or two layers), as indicated in Table 1. The acronym designation adopted for the specimens was as follows: “C” represents corrosion pre-damage, the number following “C” stands for degree of corrosion of stirrups before strengthening, “L” means PET warping, and the last number corresponds to the number of warping layers. For example, specimen “C-10-L-2” is the RC column with expected degree of corrosion of stirrups of 10%, which was warped by two layers of PET fiber.

Table 1. Parameters of test specimens.

Specimens	Strengthening	Targeted corrosion ratio (%)	PET layers
C-0-L-0	No	0	0
C-0-L-1	Yes	0	1
C-10-L-0	No	10	0
C-10-L-1	Yes	10	1
C-10-L-2	Yes	10	2
C-15-L-0	No	15	0
C-15-L-1	Yes	15	1
C-15-L-2	Yes	15	2
C-25-L-0	No	25	0
C-25-L-1	Yes	25	1
C-25-L-2	Yes	25	2

The column had a cross section of 250 mm × 250 mm and a total height of 740 mm. The corners of columns to be strengthened were rounded with a rounding radius of 20 mm. The footings had a size of 700 mm × 450 mm × 360 mm (length × width × height). Each specimen used eight 25-mm deformed bars for longitudinal reinforcement and 10-mm plain bars for stirrups spaced at 100 mm. Span-to-effective depth ratio was equal to 2.89. The longitudinal reinforcements in the columns were extended

into the footing with a sufficient anchorage length. Details of the reinforcement arrangement are shown in Figure 1.

Figure 1. Geometry and reinforcement information of specimens (unit: mm).

2.2 Material properties

Same batch of ready-mixed concrete was used to cast the specimens. The 28-day cubic (150 mm × 150 mm × 150 mm) compressive strength of concrete was 32.7 MPa. The epoxy resin used for PET warping had a tensile strength of 41.0 MPa, elastic modulus of 2.6 GPa, and an elongation at break of 1.6%, as provided by the manufacturer. Tables 2 and 3 show the properties of the reinforcement and PET fiber sheet used in this experiment obtained through uni-axial tensile coupon test.

Table 2. Mechanical properties of steel bars.

Bars	Diameter (mm)	Yield stress (MPa)	Ultimate stress (MPa)	Extension ratio (%)	Tensile modulus (MPa)
Longitudinal bar	25	476	580	38.2	2.12×10^5
Stirrup	10	342	499	36.2	2.03×10^5

Table 3. Mechanical properties of PET sheet.

Name	Tensile strength f_{tu} (MPa)	Tensile modulus E_f (GPa)	Ultimate strain (%)	Area density r (g/m ²)	Thickness (mm)
PET	719	9.35	≥7%	1161	0.841

2.3 Accelerated corrosion procedure

In order to reduce the experimental time to match the corrosion process and behavior happened in real RC members, an accelerated corrosion procedure suggested by Xia et al. (2011) was applied. In the electro-migration phase, chloride ions were electro-migrated into the concrete cover using an

electrochemical method. A constant voltage of 30 V was then applied between the outside stainless steel nets and the embedded stainless steel sheets using a DC power source. A wetting–drying cycle process was used immediately after the electro-migration process. Each cycle of the wetting–drying process involved 3 days of drying followed by 4 days of wetting in 5% NaCl solution. A current density of 0.20 mA/cm² was applied through the stirrups (acting as the anode) and the stainless steel nets (acting as the cathode). The specimens were corroded within 300-mm portion of the plastic hinge zone. The longitudinal reinforcement was coated with epoxy paint at its intersection with stirrup to inhibit corrosion. The estimated time for corrosion was calculated based on Faraday's law. The wetting–drying cycles lasted for 7, 10, and 16 weeks for the expected degree of corrosion of 10%, 15%, and 25%, respectively.

2.4 Instrumentation and testing procedure

As shown in Figure 2, the specimens were subjected to a combination of cyclic horizontal load and constant axial load. The compressive vertical load represents the service and dead load of superstructures and equals to 180 kN, which is about 30% of the expected axial loading capacity of un-corroded control column. A 500-kN closed-loop MTS actuator was used to apply the horizontal cyclic load. The cyclic tests were first conducted under load control for load cycles at 20-kN intervals until the load reached 140 kN, which was equal to the predicted yielding load of control beams. The horizontal load was adopted to control the loading procedure. In the second phase, the specimens were loaded cyclically under displacement control at 5-mm intervals until the failure of the specimens. The horizontal displacement of the actuator was adopted to control the loading procedure. Load and displacement can be controlled and recorded during the tests by a computer connected to the hydraulic actuator.

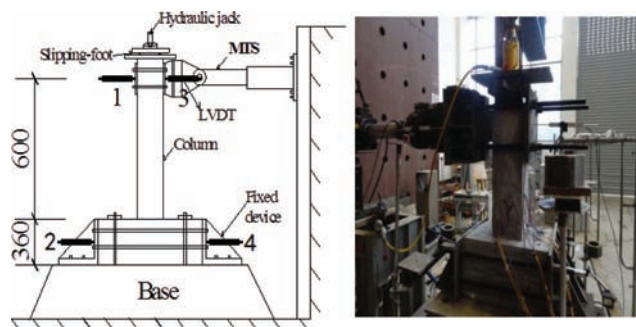

Figure 2. Illustration of loading apparatus.

Two transducers (LVDT) were mounted on the rigid frames to measure lateral displacement of columns. Two LVDTs were mounted at the footing to measure horizontal slip and rotation of the footing, as indicated in Figure 3.

Figure 3. Typical hysteric response of specimen.

3. RESULTS AND DISCUSSIONS

3.1 Corrosion damage

After the accelerated corrosion process, cracks due to corrosion were observed for series. The corrosion cracks were primarily horizontal at the locations of the stirrup with the secondary cracks that were oriented along the longitudinal reinforcement. The corrosion cracks were associated with rust stains while no delamination of the concrete cover appeared for all the corroded specimens.

After loading the test specimens to failure, the stirrups were extracted. All damage states exhibited significant areas of pitting. The damage for specimens of 10% and 15% expected corrosion ratio was localized section loss with some uniform section loss. The damage for specimens of 25% expected corrosion ratio showed significant localized and uniform section loss. The section loss was mainly on the outward facing side of bar and generally was greater at or near the bends in the stirrups. Four coupons with a length of 100 mm within the targeted 300-mm long corrosion area per stirrup per column were cleaned and used for the purpose of calculating mass loss following the ASTM G1-03 (2011). The weight of the stirrup without corrosion was determined by weighing the 100-mm long stirrup in the un-corroded zone of the same column such that the weight of the extracted coupons after corrosion could be compared to the original weight and the mass loss due to corrosion could be estimated. The average measured mass loss (degree of corrosion) and its standard deviation in the stirrups of the corroded columns are listed in Table 4. It can be concluded that the expected mass losses were achieved in the laboratory.

Table 4. Summary of test results.

Specimens	Average corrosion degree η_{ave} (%)	Diagonal cracking load P_c (kN)	Peak load P_{max} (kN)	Accumulated energy dissipation E_{sum} (kN × m)
C-0-L-0	0	50.2	185.0	63.6
C-0-L-1	0	80.2	245.0	135.3
C-10-L-0	10.66	53.4	160.3	41.9
C-10-L-1	9.91	87.2	198.1	131.1
C-10-L-2	11.2	90.3	209.7	148.6
C-15-L-0	15.63	47.6	169.8	43.9
C-15-L-1	16.26	91.4	181.5	115.9
C-15-L-2	16.82	92.7	211.9	122.4
C-25-L-0	21.66	55.6	140.0	44.1
C-25-L-1	22.78	86.1	191.7	162.8
C-25-L-2	19.86	86.7	195.1	133.6

3.2 Failure mode

All un-strengthened specimens showed brittle shear-compression failure with extensive X-shaped diagonal concrete shear cracks together with the spalling or crushing of cover concrete. For all PET strengthened specimens, the PET fiber sheet showed no breakage till the end of the test, although some parts were found debonding from the concrete surface, while crushing of concrete was also observed after removing the PET

sheet. For all the specimens, no buckling of longitudinal reinforcements was observed.

3.3 Hysteretic response and energy dissipation ratio

Due to space limitation, the sample hysteretic responses of several tested specimens are shown in Figure 3. The skeleton curve of all the specimens are presented in Figure 4. The lateral load at the first diagonal crack (P_c) and the maximum load (P_{max}) are summarized in Table 4.

Energy dissipation ratio has been used to evaluate the energy dissipation ability of structures under cyclic loading. The energy dissipation ratio at each load cycle of each specimen was calculated using Eq. (1). The accumulated energy dissipation (E_{sum}) is calculated using Eq. (2).

$$E_r = \frac{S_{(ABC+CDA)}}{S_{(OBE+ODF)}} \tag{1}$$

$$E_{sum} = \sum_{i=1}^n (E_i) \tag{2}$$

where E_i is the energy dissipation of i th load cycle, E_{sum} is the accumulated energy dissipation, and n is the number of loading cycles. The accumulated energy dissipations of test specimens are presented in Table 4.

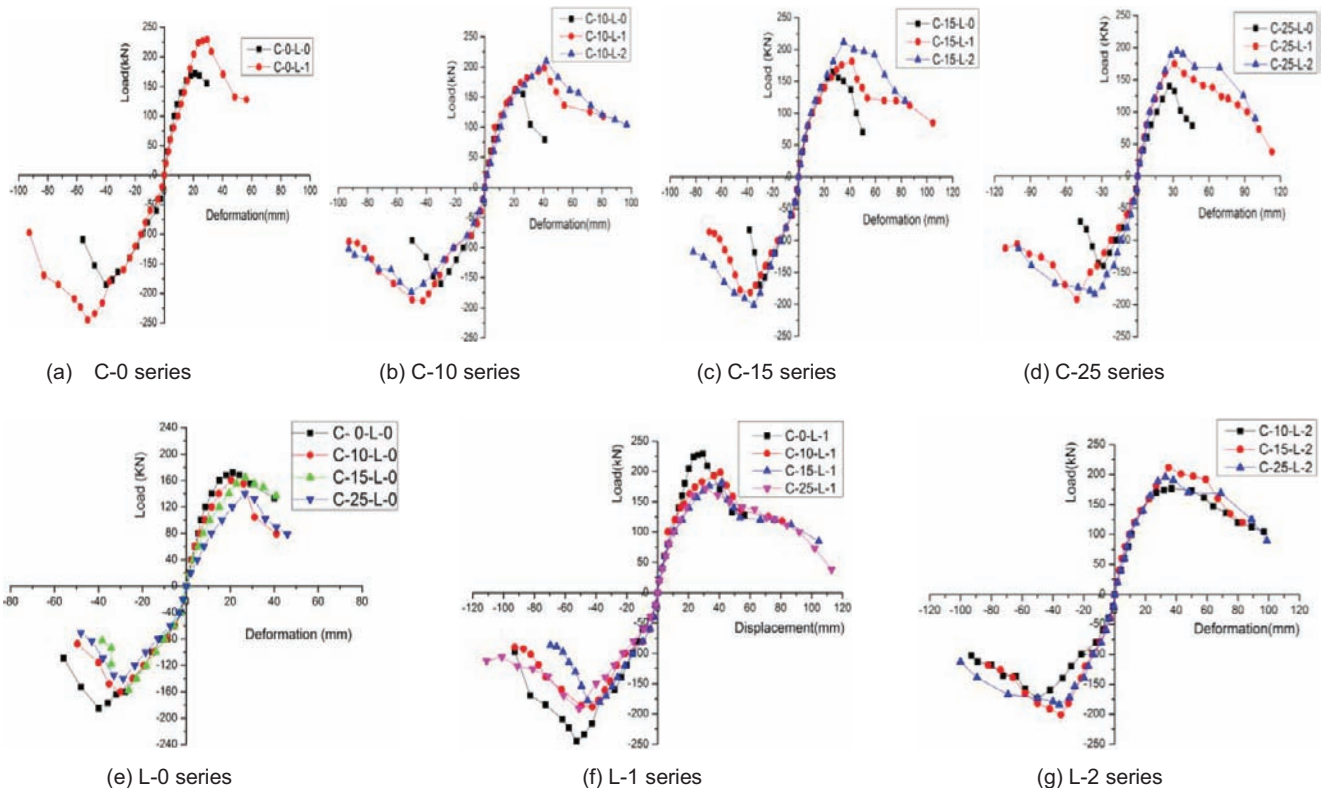

Figure 4. Skeleton curves of the test specimens.

3.4 Effect of stirrup corrosion

Figure 4 shows the lateral load–displacement skeleton curves of all the specimens and the corresponding diagonal cracking load and peak load are listed in Table 4. For un-strengthened columns, diagonal cracking of concrete web occurred at lower loads. The un-corroded specimens exhibited higher stiffness after diagonal cracking than corroded specimens. The stiffness degradation in the corroded specimens can be attributed to the corrosion cracking and loss of bond between the corroded stirrups and concrete.

As shown in Figures 5–7, for both un-strengthened and strengthened columns, the diagonal cracking load varied and the peak load and accumulated energy dissipation decreased with the increase of degree of stirrup corrosion. The corrosion of the stirrups caused deterioration of the bond between the concrete and the stirrups, and cover concrete cracking, which reduced the effective concrete area for load bearing and energy assumption.

3.5 Effect of PET warping

The un-strengthened specimens showed brittle behavior after the peak load, while the specimens with PET warping showed sudden drop of load carrying capacity after the peak load to a certain level and

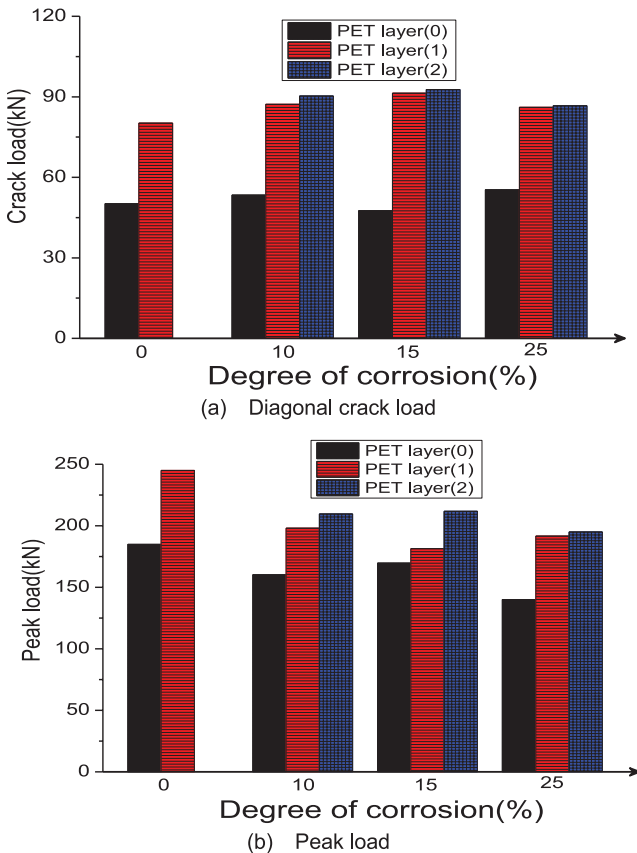

Figure 5. Effect of stirrup corrosion.

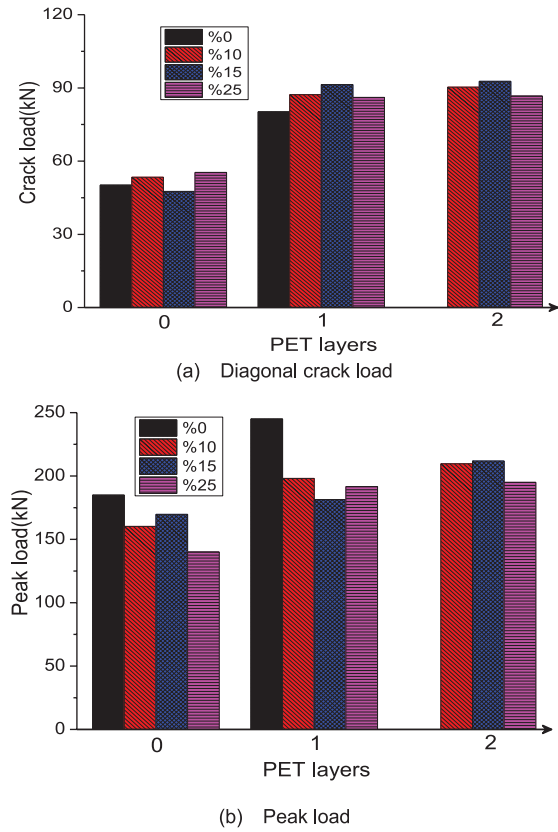

Figure 6. Effect of PET area.

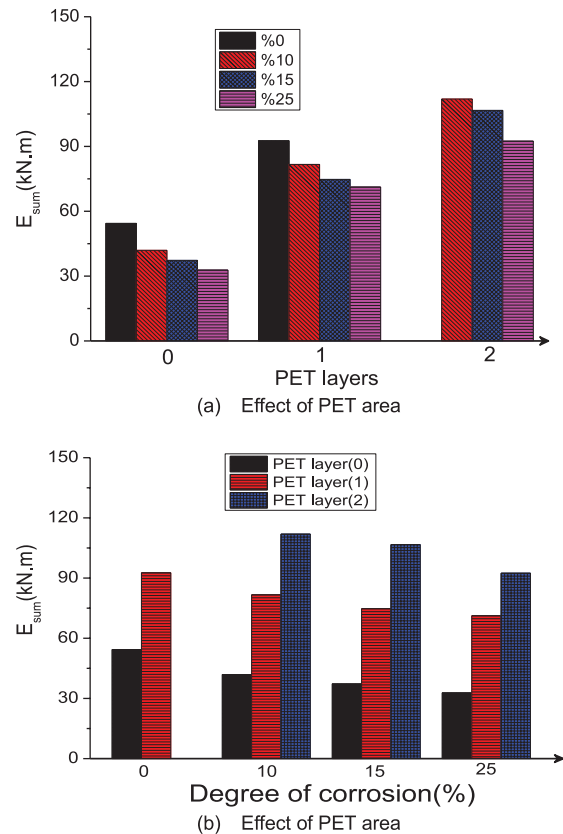

Figure 7. Accumulate energy dissipation.

then exhibited a ductile response. The peak load was reached after the yielding of stirrups, which caused crushing of cover concrete. As shown in Figures 5–7 and Table 4, the peak load and the accumulated energy dissipation after PET warping comparing to the un-strengthened columns with similar degree of stirrup corrosion was enhanced, while the diagonal cracking load differed little. The enhancement was more obvious with the increase of number of PET layers. The effect of stirrup corrosion on the peak load was reduced after the PET warping. Although the specimens were designed with insufficient shear capacity, the PET confinement could provide additional shear capacity and confinement to the concrete, which delayed the crushing of concrete and could still carry the shear force after that.

4. CONCLUSION

This paper presented the experimental study on the influence of PET warping on shear performance of RC columns with stirrup corrosion before strengthening. The following conclusions can be drawn:

1. For un-strengthened columns, the diagonal cracking load varied, while the peak load, ductility ratio, and energy dissipation ratio decreased with the increase of degree of stirrup corrosion.
2. The diagonal cracking load, peak load, and accumulated energy dissipation after PET warping comparing to the un-strengthened columns with similar degree of stirrup corrosion was enhanced. The enhancement was more with the increase of number of PET layers.
