### Abstract.

Assume we are given an  $n \times n$  binary image containing horizontally convex features; i.e., for each feature, each of its row's pixels form an interval on that row. In this paper we consider the problem of assigning topological numbers to such features; i.e., assign a number to every feature  $f$  so that all features to the left of  $f$  in the image have a smaller number assigned to them. This problem arises in solutions to the stereo matching problem. We present a parallel algorithm to solve the topological numbering problem in  $O(n)$  time on an  $n \times n$  mesh of processors. The key idea of our solution is to create a tree from which the topological numbers can be obtained even though the tree does not uniquely represent the "to the left of" relationship of the features.

**Key Words** - image processing, mesh-connected processor array, parallel computation, stereo matching, topological sorting, tree computation

## I. Introduction

Assume we are given an  $n \times n$  binary image in which we refer to the image positions containing a '1' (resp. '0') as containing a 1-pixel (resp. 0-pixel). The connected components, which we call *features*, formed by the 1-pixels are *horizontally convex*; i.e., for each feature, each of its row's 1-pixels are contiguous on that row or, equivalently, form an interval on that row. An example of an image containing a horizontally convex feature is shown in Figure 1.

A horizontally convex feature

Figure 1

Observe that the features do not need to be vertically convex. For horizontally convex features the relationship "to the left of" defines a partial order as follows. A feature  $f$  is *to the left of* a feature  $g$ , denoted  $f \prec g$ , if and only if a 1-pixel of  $f$  is to the left of a 1-pixel of  $g$  on some row of the image. If no such row exists then  $f$  and  $g$  are *incomparable*. The *topological numbering problem* is to assign to every feature in the image a unique number so that for any feature  $f$ , all features to the left of  $f$  have a smaller number assigned to them. The need for topological numbering of features arises in solutions to the stereo matching problem [1]. In this paper we present a parallel algorithm that determines the topological numbers in  $O(n)$  time when the image is stored in an  $n \times n$  mesh of processors, one pixel per processor.

We next explain briefly how the topological numbering problem arises in the context of the stereo matching problem. In the stereo matching problem we are given two images,  $L$  and  $R$ , of a 3D scene and the objective is to determine the coordinates  $(x,y,z)$  of a point in the 3D scene from its image points  $(x_l, y_l)$  in  $L$  and  $(x_r, y_r)$  in  $R$ . The heart of the stereo matching problem is finding corresponding points in the two images of the same scene [2, 3, 4, 5]. An elegant

dynamic programming solution is given by Ohta and Kanade [1]. One of the subproblems that needs to be solved in their algorithm is that of establishing precedence between horizontally convex features of an image by assigning topological numbers to them. The sequential algorithm given in [1] for numbering features is based on performing a topological search on a directed acyclic graph. The directed acyclic graph is obtained by making every feature a vertex and introducing a directed edge from  $f$  to  $g$  if  $f \prec g$  and there exists at least one row in which no other feature is met when going from  $f$  to  $g$  on that row. The so obtained directed acyclic digraph has at most  $O(n^2)$  vertices and  $O(n^2)$  edges and a topological search on it correctly numbers the features. If topological numbers are obtained for both images  $L$  and  $R$ , then they are used to enforce consistency in the matching process as follows. If the algorithm decides to match feature  $f_i$  of  $L$  with feature  $f_r$  of  $R$ , then all features in  $L$  with a smaller number than  $f_i$  can only be matched with features in  $R$  that have a smaller number than  $f_r$ .

In the next section we describe our algorithm that determines the topological numbers in  $O(n)$  time when the  $n \times n$  image is stored in an  $n \times n$  mesh of processors with one pixel per processor. We assume the mesh to be an SIMD (Single Instruction, Multiple Data) machine in which every processor has a fixed (i.e.  $O(1)$ ) amount of local storage [6]. Our algorithm determines the topological numbers by solving a graph problem. Its basic idea is quite different from the one used by Ohta and Kanade [1]. We cannot afford to parallelize the topological sort on that directed acyclic graph since topological sorting on such a graph does not seem to lend itself to an efficient parallel solution. Instead, in our solution we construct from the image a rooted, directed in-tree and we obtain the topological numbers by performing computations on that tree.

## II. The Algorithm

Throughout we will index the processing elements (PEs) of the mesh by either their row-major index or by their row/column position. Figure 2 illustrates the row-major indexing scheme. The PE at row  $i$  and column  $j$  is denoted by  $PE(i, j)$ . We let position  $(0,0)$  of the mesh (and thus the image) be the top left PE of the mesh. The input to our algorithm is an  $n \times n$  binary image  $I$ , where  $I(i, j)$  is stored at  $PE(i, j)$ . Our algorithm assumes that every PE containing a 1-pixel also contains the connected component number of the corresponding feature. We further-

A 4x4 mesh with row-major indexing

Figure 2

more assume that the component numbers are assigned so that the number of a feature is the largest row-major index of any PE containing a 1-pixel from that feature. That is, the number of a feature is the row-major index of the lowest rightmost 1-pixel in it. Numerous parallel mesh algorithms to label the connected components in  $O(n)$  time are known [7, 8, 9, 10, 11] and they can easily be modified to label the features as needed by our algorithm. We refer to the component number stored at  $PE(i,j)$  as  $C(i,j)$ . The output of our algorithm is array  $TN$ , where  $TN(i,j)$  contains the topological number of the feature containing the 1-pixel at position  $(i,j)$ .

One seemingly obvious algorithm for determining the topological numbers is based on the "sweepline" method. A vertical line is used to sweep the image, for example, from right to left.

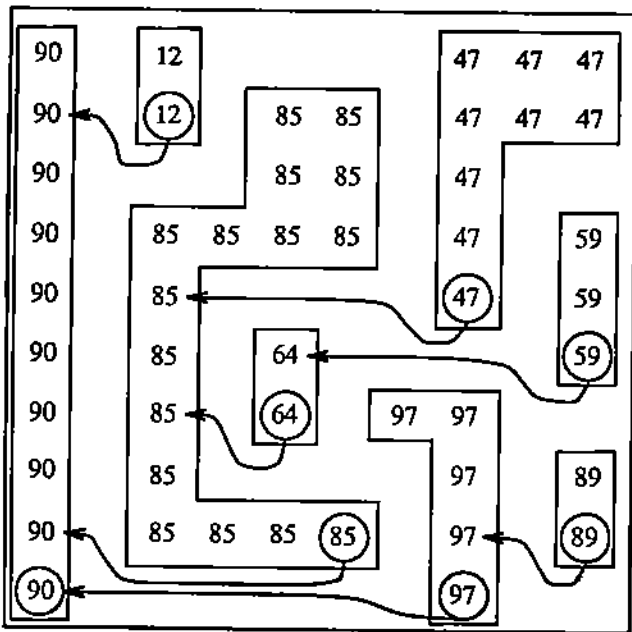

Illustrating why a "sweepline" method does not work

Figure 3

The first time a 1-pixel of a feature  $g$  is encountered, it is given a topological number such that feature  $g$  is given a larger number than feature  $f$  if and only if feature  $g$  is encountered before feature  $f$  in the right-to-left sweep. An image on which the method fails is shown in Figure 3.

Our algorithm consists of three steps which are described next. In the first step it creates from the input image  $I$  a rooted, directed in-tree  $T$  in which the features correspond to the vertices. We create a root vertex which corresponds to an artificially created feature running along the length of the left border of the input image (introducing this "dummy" feature simplifies the exposition). The edges of the tree are created as follows. If  $PE(i,j)$  contains a component number equal to its row-major index, then  $PE(i,j)$  initiates a horizontal scan leftward on row  $i$ . The component number is taken along on this scan. In Figure 4(a), the processors initiating such a scan are circled. Thus a processor initiates a scan if and only if it contains the lowest right-most 1-pixel of a feature.

(a) Features indicated by component numbers; arrows show scans done in step 1

(b) Rooted directed tree created from (a) with preorder and component numbers

Figure 4

From now on we will refer to the largest row number (i.e. geometrically lowest row) containing 1-pixels belonging to feature  $f$  as  $low(f)$ . For example, in Figure 4(a),  $low(12)=1$ , and  $low(47)=4$ . If feature  $f$  contains more than one 1-pixel in  $low(f)$ , then the scan may travel through other 1-pixels belonging to  $f$ . The scan initiated at  $PE(i,j)$  stops when it reaches the

first 1-pixel belonging to a different feature  $g$ . For example, in Figure 4(a), the scan initiated at the circled '85' stops at the tip of the arrow starting from it (i.e., at a '90'). If the scan stops at  $PE(i, j')$ ,  $j' < j$ , the directed edge  $(C(i, j), C(i, j'))$  is created in the  $PE(i, j')$ . The graph created in this step is an acyclic digraph in which every node has out-degree exactly one, except one node which has out-degree zero (the "dummy" feature, labeled '90' in Figure 4(a)). It is easy to see that this graph is actually a directed in-tree rooted at the node of out-degree zero. Figure 4(b) shows the tree created from 4(a). In Figure 4(b), notice that the children of any node are drawn from left to right by increasing component numbers. Thus  $T$  is an ordered tree.

The rooted, directed in-tree created by our algorithm does not contain all the information about the partial order. Figure 5 illustrates three distinct partial orderings that give rise to the same tree.

Illustrating distinct partial orderings that give rise to the same tree

Figure 5

Contrast this with the directed acyclic graph of Ohta and Kanade [1], whose transitive closure is exactly the " $\prec$ " relationship. However, the tree created in our algorithm contains all of the crucial information needed to compute the topological numbers, and the simple structure of a tree allows us to generate these numbers in  $O(n)$  time.

The second step of the algorithm takes the rooted, directed in-tree  $T$  and computes the preorder numbers of the vertices of  $T$  using the Atallah-Hambrusch algorithm given in [12]. When computing the preorder numbers it is crucial that the children of every node are visited in the order of increasing component numbers. As we will show in the next section, for any two features  $f$  and  $h$  with  $f \prec h$ , the preorder number of  $f$  is smaller than the preorder number of  $h$ . Hence, the preorder numbers are correct topological numbers. The preorder numbers for the

tree shown in Figure 4(b) are given inside the circles indicating the vertices. After the preorder numbers have been assigned, the final step of the algorithm broadcasts them from the vertices of  $T$  to all 1-pixels of the corresponding features in  $I$ , thus creating the array  $TN$ . This "broadcasting" is done in  $O(n)$  time using methods described in [8, 10, 11].

### III. Correctness

In this section we prove the correctness of the algorithm outlined in the previous section. We denote the preorder number assigned to feature  $f$  as  $\text{pre}(f)$ . Recall that in the algorithm preorder numbers are assigned to the vertices such that if a vertex has two children  $u$  and  $v$  and  $u < v$ , then  $\text{pre}(u) < \text{pre}(v)$  (i.e., vertex  $u$  is visited before vertex  $v$  in the traversal). Before showing that the preorder numbers are topological numbers, we introduce the notion of an image path, and then give a lemma.

Let  $w_0, w_1, \dots, w_{k-1}, w_k$  be the vertices on the path from feature  $w_0$  to  $w_k$  in  $T$ . The *image path*  $P(w_0, w_k)$  consists of all the 1-pixels in feature  $w_0$ , all the 1-pixels in feature  $w_i$  that are on a row greater or equal to  $\text{low}(w_{i-1})$ ,  $1 \leq i \leq k$ , and of all the 0-pixels traversed during the horizontal scan from feature  $w_i$  to  $w_{i+1}$ ,  $0 \leq i \leq k-1$ . See Figure 6 for an example of an image path  $P(w_0, w_3)$ .

Example of an image path  $P(w_0, w_3)$ ; image path includes shaded portions of the features and of the 0-pixels.

Figure 6

Observe that the set of pixels included in an image path is connected and horizontally convex.

**Lemma.** Let  $P(w_0, w_k)$  and  $P(u_0, u_l)$  be two image paths such that the  $w_0$ -to- $w_k$  path in  $T$  is disjoint from the  $u_0$ -to- $u_l$  path in  $T$ . Then there cannot exist a 1-pixel that is in both  $P(w_0, w_k)$  and  $P(u_0, u_l)$ .

**Proof.** Assume there exists such a 1-pixel. Let  $x$  be this 1-pixel. The feature to which  $x$  belongs is in both the  $w_0$ -to- $w_k$  and the  $u_0$ -to- $u_l$  path in  $T$ , a contradiction.  $\square$

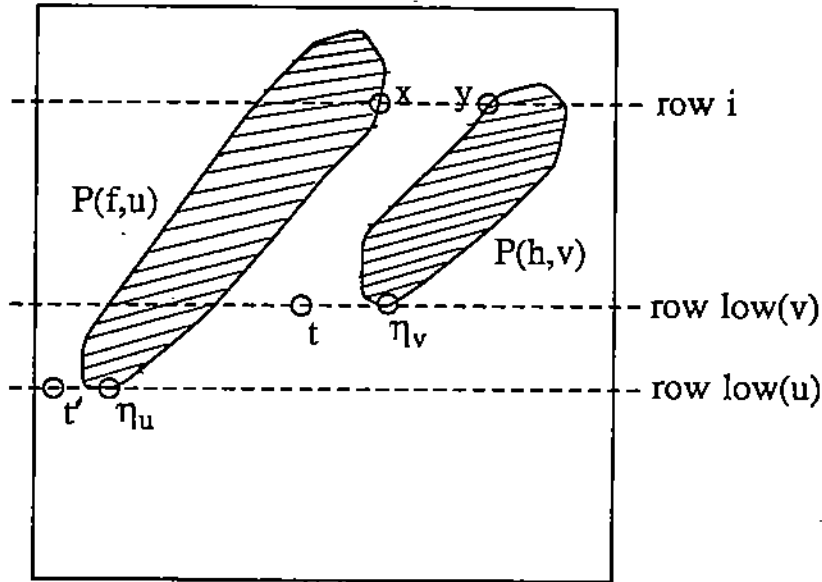

**Theorem.** For any two features  $f$  and  $h$  with  $f \prec h$ , we have  $\text{pre}(f) < \text{pre}(h)$ .

**Proof.** Let  $f$  and  $h$  be any two features with  $f \prec h$ . Note that feature  $f$  cannot be descendant of  $h$  in  $T$ , since this would imply  $h \prec f$ , contradicting  $f \prec h$ . If  $h$  is a descendant of  $f$  in  $T$ , then, due to the definition of preorder numbering, feature  $f$  is assigned a smaller preorder number than feature  $h$  and the theorem follows.

Assume now that neither of  $\{f, h\}$  is a descendant of the other in  $T$ . Let  $d$  be the common ancestor of  $f$  and  $h$  that is lowest in  $T$  (i.e., farthest from the root in  $T$ ). Let  $u$  and  $v$  be the two children of  $d$  such that  $f$  is a descendent of  $u$  and  $h$  is a descendent of  $v$ . To show that  $\text{pre}(f) < \text{pre}(h)$ , it suffices to show that  $\text{low}(u) < \text{low}(v)$ , since this would imply that  $u$  occurs before  $v$  in the ordered list of  $d$ 's children (i.e., it would imply  $u < v$ ). This in turn would imply that the preorder traversal visits  $u$  and its subtree before  $v$  and its subtree, and hence that  $\text{pre}(f) < \text{pre}(h)$ . We now show that  $\text{low}(u) < \text{low}(v)$ .

Assume by contradiction that  $\text{low}(u) \geq \text{low}(v)$ . If  $\text{low}(u) = \text{low}(v)$ , then  $u$  and  $v$  cannot both be children of  $d$  in  $T$ , and therefore  $\text{low}(u) > \text{low}(v)$ . Since  $f \prec h$ , there exists a row  $i$  such that a 1-pixel  $x$  of  $f$  is to the left of a 1-pixel  $y$  of  $h$ . Let  $\eta_u$  (resp.  $\eta_v$ ) be the rightmost 1-pixel of  $u$  (resp.  $v$ ) in row  $\text{low}(u)$  (resp. row  $\text{low}(v)$ ). Figure 7 shows  $x, y, \eta_u, \eta_v$ , and the relative positions of the image paths  $P(f, u)$  and  $P(h, v)$ . In particular,  $P(f, u)$  contains the pixels  $x$  and  $\eta_u$ ,  $P(h, v)$  contains the pixels  $y$  and  $\eta_v$ , and  $\eta_v$  is to the right of  $P(f, u)$ . (If  $\eta_v$  was to the left of  $P(f, u)$ , then  $P(f, u)$  and  $P(h, v)$  would intersect, violating the previous lemma.)

Since  $d$  is the parent of  $v$  in  $T$ , there is a 1-pixel of  $d$  in between  $P(f, u)$  and  $\eta_v$  on row  $\text{low}(v)$ . Let  $t$  be such a 1-pixel. Since  $d$  is also the parent of  $u$ , there is a 1-pixel of  $d$  to the left of  $P(f, u)$  on row  $\text{low}(u)$ . Let  $t'$  be such a pixel. Figure 7 shows both  $t$  and  $t'$ . Since  $d$  is horizontally convex, the only way for  $t$  and  $t'$  to be in the same feature  $d$  is for  $d$  to cross  $P(f, u)$ .

Example of two image paths,  $P(f,u)$  and  $P(h,v)$ ; pixels  $x$ ,  $y$ ,  $\eta_u$ ,  $\eta_v$ ,  $t$ , and  $t'$  are circled and labeled.

Figure 7

This is not possible and thus we have  $\text{low}(u) < \text{low}(v)$ .  $\square$

#### IV. Implementation

We now show that each step of the algorithm can be implemented in  $O(n)$  time on a mesh of size  $n \times n$ . All of the leftward scans are obviously completed within  $n$  time steps. It is also easy to see that at most one edge  $(C(i,j), C(i,j'))$  is created in  $PE(i,j')$ . This holds since, for a 1-pixel located at position  $PE(i,j')$  belonging to a feature  $f$ , there is at most one  $PE(i,j)$  containing a 1-pixel belonging to a different feature  $g$  immediately to the right of  $PE(i,j')$  on row  $i$ . Once the rooted, directed in-tree  $T$  has been created, we use the algorithm described in [12] to assign the preorder numbers to the vertices of the tree in  $O(n)$  time. The algorithm in [12] assigns preorder numbers to the vertices of  $T$  in the manner required by our algorithm; i.e., for any vertex in  $T$  with children  $u$  and  $v$ ,  $u$  is visited before  $v$  if and only if  $\text{low}(u) < \text{low}(v)$ . The input to the preorder algorithm consists of the edges of  $T$  as stored in the PEs after the leftward scans have been completed. If edge  $(C(i,j), C(i,j'))$  is stored in  $PE(i,j')$  before the preorder numbering occurs, then we can assume that the preorder algorithm returns  $(C(i,j), C(i,j'))$  to  $PE(i,j')$ . In addition, we can assume that the preorder algorithm returns to  $PE(i,j')$  the topologi-

cal number for the feature that contains the 1-pixel at  $PE(i,j)$ .

The final step is to broadcast the preorder number stored in  $PE(i,j')$  to all 1-pixels of the corresponding feature. The broadcasting can be done in  $O(n)$  time in a number of ways. One way of implementing the final step first sends the preorder number from  $PE(i,j')$  rightward to  $PE(i,j)$ . The array  $TN$  is then created by performing a connected component computation which accomplishes the broadcast. This concludes the description of our  $O(n)$  time algorithm for determining the topological numbers of features.

## V. Conclusion

In this paper we gave an  $O(n)$  time algorithm for topologically numbering horizontally convex features of an  $n \times n$  binary image on an  $n \times n$  mesh of processors. The topological numbering problem is to assign to every feature in the image a unique number so that all features to the left of a feature  $f$  have a smaller number assigned to them. Our algorithm solves this problem by constructing a rooted, directed in-tree from the image and by determining the preorder numbers of the constructed tree.
