ABSTRACT

We report results from a 30 ks observation of Cygnus X-1 with the High Energy Transmission Grating Spectrometer (HETGS) on board the *Chandra X-Ray Observatory*. Numerous absorption lines were detected in the HETGS spectrum. The lines are associated with highly ionized Ne, Na, Mg, Al, Si, S, and Fe, some of which have been seen in earlier HETGS observations. Surprisingly, however, we discovered dramatic variability of the lines over the duration of the present observation. For instance, the flux of the Ne x line at 12.14 Å was about 5×10^{-3} photons cm^{-2} s^{-1} in the early part of the observation but became subsequently undetectable, with a 99% upper limit of 0.06×10^{-3} photons cm^{-2} s^{-1} on the flux of the line. This implies that the line weakened by nearly 2 orders of magnitude on a timescale of hours. The overall X-ray flux of the source did also vary during the observation but only by 20%–30%. For Cyg X-1, the absorption lines are generally attributed to the absorption of X-rays by ionized stellar wind in the binary system. Therefore, they may provide valuable diagnostics on the physical condition of the wind. We discuss the implications of the results.

Subject headings: binaries: general — black hole physics — stars: individual (Cygnus X-1) — stars: winds, outflows — X-rays: binaries

1. INTRODUCTION

Cygnus X-1 is the first dynamically determined black hole system (Webster & Murdin 1972; Bolton 1972). It is in a binary system with a massive O9.7 Iab supergiant, and the orbital period was determined optically to be 5.6 days. Cyg X-1 is thus intrinsically different from the majority of known black hole candidates (BHCs) whose companion stars are much less massive (see review by McClintock & Remillard 2006). Curiously, those that have a high-mass companion (including Cyg X-1, LMC X-1, and LMC X-3) are all persistent X-ray sources, while those that have a low-mass companion are exclusively transient sources. Perhaps stellar wind from the companion star plays a significant role in this regard (Cui et al. 1998a).

Unlike transient BHCs, in which mass accretion is mediated by the companion star overfilling its Roche lobe, Cyg X-1 is thought to be a wind-fed system. In this case, however, the wind is thought to be highly focused toward the black hole, since the companion star is nearly filling its Roche lobe (Gies & Bolton 1986). The observed orbital modulation of the X-ray flux (Wen et al. 1999; Brocksopp et al. 1999a) has provided tentative evidence for wind accretion because it is probably caused by a varying amount of absorption through the wind (Wen et al. 1999). On the other hand, it is generally believed that an accretion disk is also present, based on the presence of an ultrasoft component, as well as an Fe Kα emission line in the X-ray spectrum (e.g., Ebisawa et al. 1996; Cui et al. 1998b).

Cyg X-1 is probably still the most studied BHC. It is a fixture in the target list for all major X-ray missions. Much has been learned from modeling the X-ray continuum of the source, as well as from studying its X-ray variability. A recent development is the availability of high-resolution X-ray data, which may shed more light on the accretion process and the environment within the binary system. Cyg X-1 has been observed on many occasions with the High Energy Transmission Grating Spectrometer (HETGS) on board the *Chandra X-Ray Observatory* and the Reflection Grating Spectrometer on board the *XMM-Newton* observatory. The high-resolution spectra have revealed the presence of numerous absorption lines that are associated with highly ionized material (Marshall et al. 2001; Schulz et al. 2002; Feng et al. 2003; Miller et al. 2005).

In this work, we report the detection of absorption lines, some of which have been seen previously but are much stronger here, and, more surprisingly, the discovery of dramatic variability of the lines, based on data from our *Chandra* HETGS observation of Cyg X-1 during its 2001 state transition. The fluxes of some of the lines varied by nearly 2 orders of magnitude over the duration of the observation, while the overall flux of the source varied only mildly.

2. OBSERVATIONS AND DATA REDUCTION

Cyg X-1 made a rare transition between the low-hard state and the high-soft state, as seen by the All-Sky Monitor (ASM) on the *Rossi X-Ray Timing Explorer* (*RXTE*), about 5 yr after a similar episode in 1996 (Cui et al. 1997a, 1997b). Figure 1 shows the ASM light curve that covers the entire period. In this case, the flux of the source stayed high for $\sim$400 days, about twice as long as in 1996. Otherwise, the two episodes are very similar, including the flux levels of the two states, prominent X-ray flares in both states, and rapid transitions.

After the ASM alert the source was observed from 2001 October 28 16:13:52 to October 29 00:33:52 (UT) with the HETGS on board *Chandra* (ObsID 3407). The HETGS consists of two gratings: the Medium Energy Grating (MEG) and the High Energy Grating (HEG). After passing the gratings, the photons are recorded and read out with the spectroscopic array of the Advanced CCD Imaging Spectrometer (ACIS). To avoid photon pileup in the dispersed events, we chose to run the ACIS in continuous-clocking (CC) mode. We also applied a spatial window around the aim point to accept every 10th event in the zeroth order, to prevent telemetry saturation yet maintain a handle on the position of the zeroth-order image for accurate wavelength calibration.

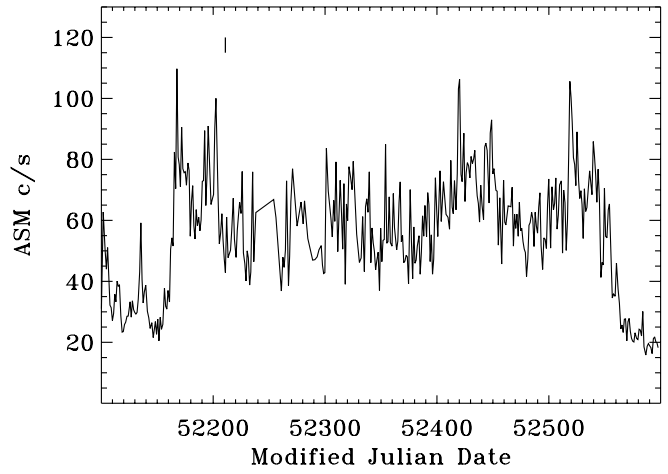

FIG. 1.—Daily averaged ASM light curve of Cyg X-1 during the 2001 state transition. The vertical line indicates the time of the *Chandra* observation.

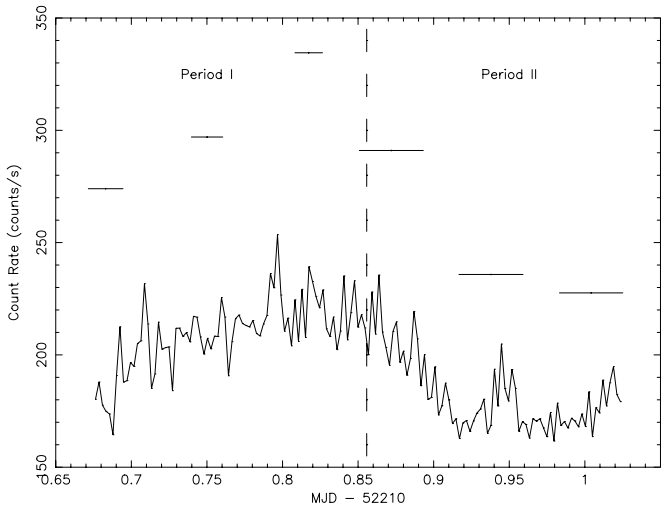

FIG. 2.—X-ray light curves of Cyg X-1. The solid curve shows data from the MEG first-order data, while the horizontal bars show the average count rates from PCU2. The error bars are negligible in both cases. The dashed line defines the two time periods for subsequent analyses (see text).

The *Chandra* data were reduced and analyzed with the standard CIAO analysis package (ver. 3.2). Following the CIAO version 3.2 Science Threads,[1] we prepared and filtered the data, produced the Level 2 event file from the Level 1 data products, constructed the light curves, and made the spectra and the corresponding response matrices and auxiliary response files (ARFs). We did have to work around a problem related to the use of `maskfile` for the CC-mode data, when we were making the ARFs. The solution is now included in the CIAO version 3.3 Science Threads. To verify wavelength calibrations, we compared the plus and minus orders and found good agreement on the position of prominent lines. We did not subtract background from either the light curves or the spectra, because it is not obvious how to select background events from the CC-mode data. For a bright source such as Cyg X-1, however, we expect the effects to be entirely negligible.

In coordination with the *Chandra* observation, we also observed Cyg X-1 with the Proportional Counter Array (PCA) and High-Energy X-Ray Timing Experiment (HEXTE) detectors on board *RXTE*. The PCA and HEXTE cover roughly the energy ranges of 2–60 and 15–250 keV, respectively. In this work, we made use of the combined broad spectral coverage of the two detectors to constrain the X-ray continuum more reliably. The *RXTE* observation was carried out in six short segments, with exposure times of 1–3 ks. The data were reduced with the standard HEASOFT package (ver. 5.2), along with the associated calibration files and background models. We followed the usual procedures[2] in preparing, filtering, and reducing the data, as well as in deriving light curves and spectra from the standard-mode data. While the HEXTE background was directly measured from off-source observations, the PCA background was estimated based on the background model appropriate for bright sources.

3. ANALYSIS AND RESULTS

3.1. *Light Curves*

Figure 2 shows the *Chandra* light curve of Cyg X-1 that is made from the MEG first-order data (with ± 1 orders co-added). For comparison, we have overplotted the average count rate of PCU2 for each of the *RXTE* exposures. The agreement is quite good. Besides showing the rapid flares and other short-term variability that are expected in Cyg X-1, the source also varies significantly on a timescale of hours. The MEG count rate rises from a baseline level of roughly 170 counts s^{-1} to a peak of roughly 220 counts s^{-1} within 3–4 hr and quickly goes back down to the baseline level. We somewhat arbitrarily divided the light curve into two time periods (which are labeled "period I" and "period II" in Fig. 2) for subsequent analyses.

3.2. *High-Resolution Spectroscopy*

We analyzed and modeled the HETGS spectra in ISIS (ver. 1.2.9; Houck & Denicola 2000).[3] For this work, we focused only on the first-order spectra because of the relatively poor signal-to-noise ratio of higher order spectra. For both the MEG and HEG, we first co-added the plus and minus orders to produce an overall first-order spectrum, again following the appropriate CIAO version 3.2 science threads. The resolution of the raw data is about 0.01 and 0.005 Å for the MEG and HEG, respectively, which represents a factor of 2 oversampling of the instrumental resolution. We applied no further binning of the data. Each spectrum was broken into 3 Å segments for subsequent analyses. Each segment was fitted locally with a model that consists of a multicolor disk component and a power law for the continuum and negative or positive Gaussian functions for narrow absorption or emission features, with the interstellar absorption taken into account. Such a continuum model is typical of BHCs. However, the best-fit continuum differs among the segments or between the MEG and HEG, presumably due to remaining calibration uncertainties. Since we are only interested in using the *Chandra* data to study lines, we think that the adopted procedure is justified. We use the *RXTE* data to more reliably constrain the continuum.

One notices right away the presence of many absorption lines in the high-resolution spectra. For this work, we consider a feature real if it is present in both the MEG and HEG data, with a significance of above 4 σ. Figure 3 shows a portion of the MEG first-order spectrum for period I, to highlight the lines detected. No absorption lines were found at wavelengths above 15 Å. We should point out that we also see the emission-like features at 6.74 and 7.96 Å, which most likely are instrumental artifacts associated with calibration uncertainties around the Si K and

[c] Unresolved.
[d] ATOMDB, ver. 1.3.1.
[e] The two transitions are equally probable. The average wavelength was used to derive the Doppler shift of the line.

Miller et al. (2005) also reported a line at 7.85 Å (Mg XI) but only at the 3 σ level. The line can also be seen in our data at the 4 σ level (but it also just misses our threshold). Therefore, we already see some indication that the absorption lines in Cyg X-1 may be variable from a comparison of our results with those published.

Still, it is surprising that almost all of the absorption lines become undetectable in period II. Figure 4 shows the MEG first-order spectrum for this time period, which can be directly compared to results in Figure 3. The only exception is the line at 14.608 Å, which is detected with a significance of 5 σ in period II.

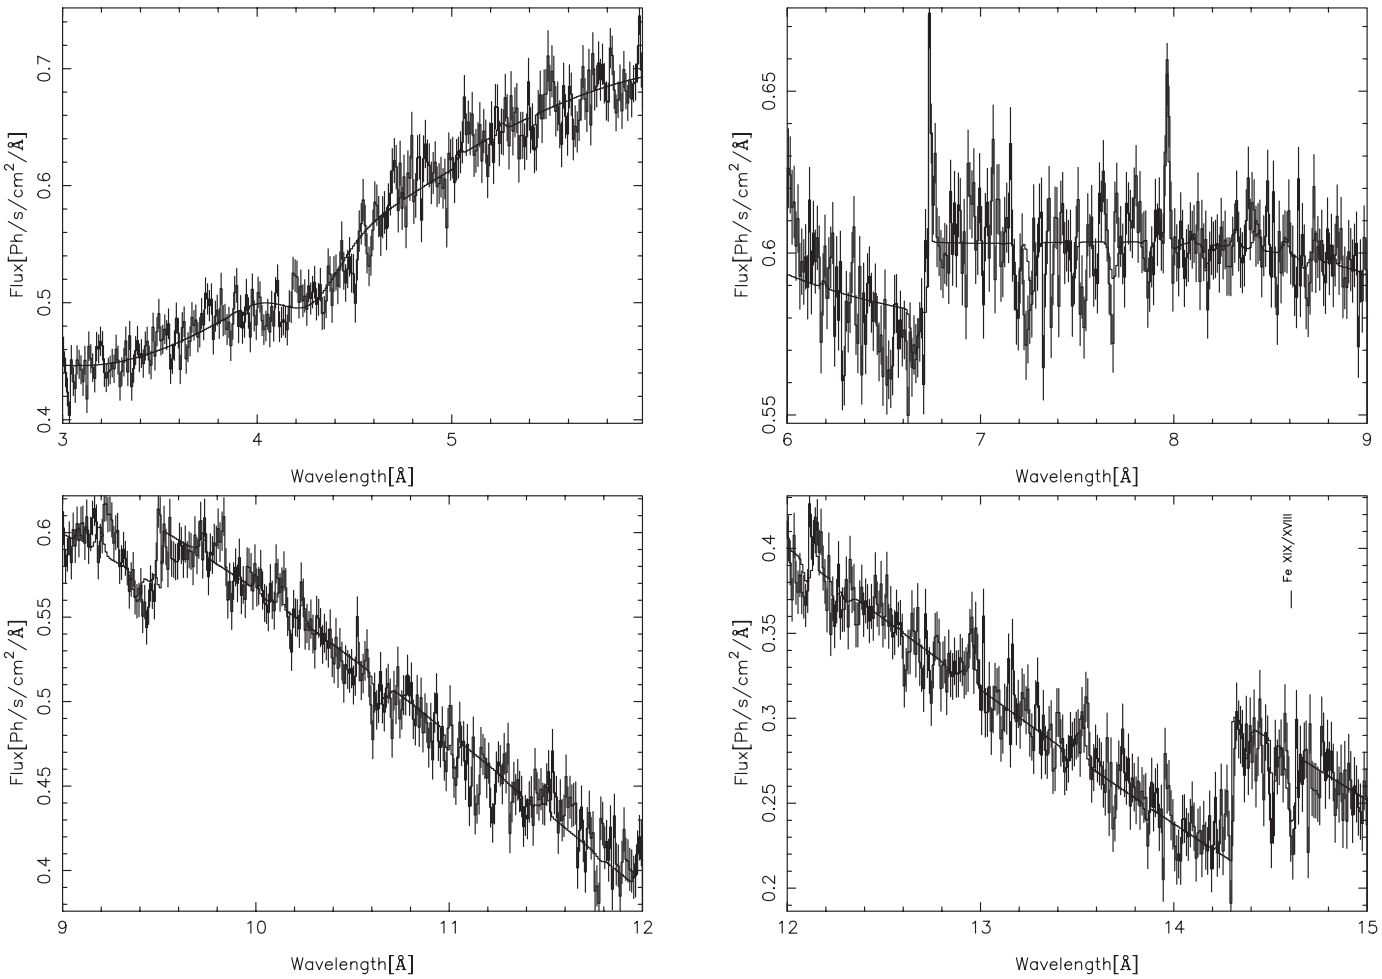

FIG. 4.—Same as Fig. 3, but for period II. Note the absence of nearly all the absorption lines seen in Fig. 3.

We derived 99% upper limits on the flux and EW of each line seen in period I but not in period II. The results are also summarized in Table 1, for direct comparison. As an example, we examine the Ne X line at 12.1339 Å in the two periods. The integrated flux of the line is about 5×10^{-3} photons cm^2 s^{-1} in period I, while its 99% upper limit for period II is only 0.06×10^{-3} photons cm^2 s^{-1}. Therefore, the line weakened by nearly 2 orders of magnitude in flux over a timescale of merely several hours. This is the first time that such dramatic variability of the lines has been observed in any BHC. While this is the most extreme case, other lines also show large variability (see Table 1).

To quantify the column density of each ion required to account for the corresponding absorption line detected and its variability, we carried out curve-of-growth analysis, following Kotani et al. (2000). The atomic data used in the analysis were again taken from Verner et al. (1996) and Behar & Netzer (2002), as well as ATOMDB version 1.3.1 in some cases. The analysis assumes that the width of the lines is due entirely to thermal Doppler broadening. For resolved lines, we derived the characteristic temperature from the measured widths. For unresolved lines, on the other hand, we adopted a temperature that would lead to a line width equal to the resolution of the MEG (0.023 Å at FWHM). In these cases, therefore, the derived column density only represents a *lower* limit. The results are shown in Table 1. This explains why, for example, the density of Ne X derived from the 12.144 Å line (which is unresolved) is significantly lower than that from the 10.245 Å line. Note, however, that the latter is much lower than that from the 9.727 Å line. We think that the inconsistency arises from the fact that the 9.727 Å line is likely a mixture of the Ne line and the Fe XIX line at 9.700 Å. Similar inconsistency is also apparent in a few other cases (see Table 1), which may originate similarly in line blending. It is also worth noting that most lines that we have analyzed fall on the linear part of the curve of growth. All *resolved* lines at wavelengths $\lambda > 11.7$ Å are saturated; so is the unresolved line at 14.203 Å. To show the degree of variability, we also derived a 99% upper limit on the column density of each of the ions for period II (assuming the same characteristic temperatures).

3.3. *X-Ray Continuum*

We now use the *RXTE* data to constrain the X-ray continuum of Cyg X-1. Both the PCA and HEXTE data were used. For the PCA, we used only data from the first xenon layer of each PCU, which is most accurately calibrated. Consequently, the PCA spectral coverage is limited to roughly 2.5–30 keV. We relied on the HEXTE data to extend spectral coverage to higher energies. The PCA consists of five detector units, known as PCUs. Not all PCUs were always operating. For simplicity, we used only data from PCU0 and PCU2, which stayed on throughout the observation, in the subsequent modeling. We chose to derive a spectrum for each PCU separately, as well as for each of the two HEXTE clusters. Residual calibration errors were accounted for by adding 1% systematic uncertainty to the data. We also rebinned the HEXTE spectra to a signal-to-noise ratio of at least 3

in each bin. The individual spectra were then jointly fitted with the same model, which includes a multicolor disk component, a broken power law that rolls over exponentially beyond a characteristic energy, and a Gaussian, taking into account the interstellar absorption. We also multiply the model by a normalization factor that is fixed at unity for PCU2 but is allowed to vary for other detectors, in order to account for any uncalibrated difference in the overall throughput among the detectors. The model fits the data well for all six segments in the sense that the reduced χ^2 is near unity (with 169 degrees of freedom).

The spectral shape of Cyg X-1 varied little from one observation to the other. The best-fit photon indices are $\sim$2.1 and $\sim$1.7 below and above $\sim$10 keV. The rollover energy stays at 20–21 keV and the *e*-folding energy roughly at 120–130 keV. Neither the disk component nor the absorption column density is well constrained by the data, due to the lack of sensitivity (and, to some extent, large calibration uncertainty) at low energies. The results can be compared directly with those of Cui et al. (1997a), who applied the same empirical model to the *RXTE* spectra of Cyg X-1 during the 1996 transition. It is quite apparent that the spectra here are significantly harder, implying that the source was certainly not yet in the true high-soft state (see Cui et al. 1997a, 1997b for discussions on the "settling period"). From the long-term ASM monitoring data, we can see that Cyg X-1 was brighter during our observation than during any of the earlier *Chandra* observations (Marshall et al. 2001; Schulz et al. 2002; Miller et al. 2005), but not as bright as during a later observation (Feng et al. 2003), when the high-soft state appears to have been reached.

3.4. *Photoionization Modeling*

To shed light on the physical properties of the absorber, we carried out a photoionization calculation with XSTAR version 2.1 kn3.[5] The underlying assumption is that the absorber is photoionized by the X-ray radiation from the vicinity of the black hole. The input parameters include the 0.5–10 keV luminosity ($L_X = 3.11 \times 10^{37}$ erg s^{-1}, for a distance of 2.5 kpc) and the power-law photon index (2.1), both of which are based on results from modeling one of the *RXTE* spectra with an assumed N_H value of 5.5×10^{21} cm^{-2} (Ebisawa et al. 1996; Cui et al. 1998b). We should note that it is in general risky to extrapolate the assumed power-law spectrum to lower energies because it could severely overestimate the flux there. For the lines of interest here, however, only ionizing photons with energies >1 keV contribute, and the spectrum of those photons is described fairly well by a power law because the effective temperature of the disk component is expected to very low (e.g., Ebisawa et al. 1996; Cui et al. 1998b).

One of the outputs of the calculation is abundances of the ions of interest, as a function of the ionization parameter, $\xi = L_X/nr^2$, where n is the density of the absorber and r is the distance of the absorber to the source of ionizing photons. Using these abundance curves, we could, in principle, constrain ξ to a range that is consistent with the ratio of the densities of any two ions of an element. The challenge in practice is, as already mentioned, that many of the lines are likely a blend of multiple transitions (of comparable probabilities), which makes it difficult to reliably determine the densities. Nevertheless, we made an attempt at deriving such constraints with the resolved, nonmixed lines. Figure 5 summarizes the results. The intervals do not all overlap, which implies that no single value of ξ could account for all the data. This is supported by the fact that we have detected all the lines that are expected for ionization parameters in the range of roughly $10^{2.5}$–$10^{4.5}$. If one assumes that the "absorbers" are thin shells along the line of sight and that they all have the same density, e.g., $n = 10^{11}$ cm^{-3} (see, e.g., Wen et al. 1999), one would have 10^{11} cm $\lesssim r \lesssim 10^{12}$ cm. Compared with the estimated distance between the compact object and the companion star ($\sim 1.4 \times 10^{12}$ cm; LaSala et al. 1998), this would put the "absorbers" within the binary system. One should, however, take the results with caution because of, for example, gross oversimplification regarding the geometry of the "absorbers."

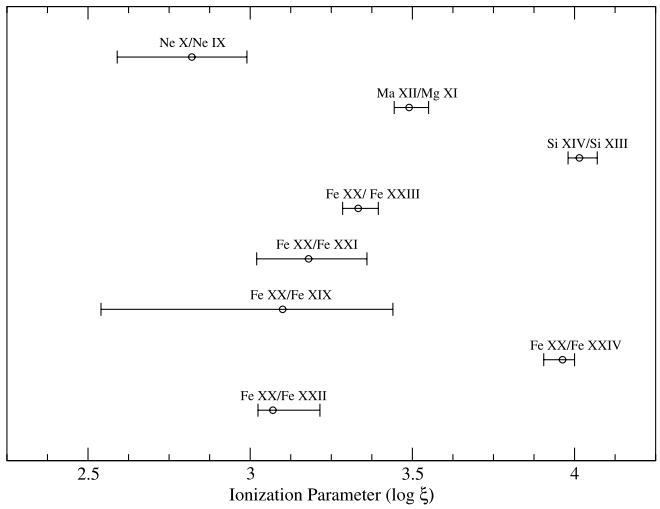

FIG. 5.—Allowed ranges of the ionization parameter, each of which is inferred from the ratio of the average densities of two ions of the same element.

4. DISCUSSION

The observed dramatic variability of the absorption lines might be caused by a change in the degree of ionization in the wind. Since the overall X-ray luminosity varied only mildly, we speculate that it probably arises from a sudden change in the density of the wind. There is evidence that such a change could occur during a state transition or during flares (Gies et al. 2003). If the moderate decrease in the ionizing flux is accompanied by a more dramatic reduction in the density of the wind from period I to period II, then the ionization parameter might increase sufficiently to cause a total ionization of the wind in period II and thus the disappearance (or significant weakening) of the lines. It is worth noting that in period I lighter elements seen are all H- or He-like but Fe is in an intermediate ionization state (as indicated by the absence of H- or He-like ions), suggesting a high but not extreme degree of ionization in the period. Conversely, a dramatic increase in the wind density could achieve the same effect. Numerical simulations of similar wind-accretion systems (e.g., Blondin et al. 1991) have revealed not only a significant jump in the column density at late orbital phases ($\gtrsim$0.6) that is associated with tidal streams but also large variability of the absorbing column. It is conceivable that period II might coincide with a sudden increase in the column density. Since we found no apparent absorption lines that correspond to a lower degree of ionization in period II, however, such lines must be outside the spectral range covered with our data, in order for the scenario to be viable. A quantitative assessment of these scenarios is beyond the scope of this work.

Many of the absorption lines detected by Miller et al. (2005) are much stronger during period I of our observation (see Table 1). Using only the lines that are detected with a significance above

[5] See http://heasarc.gsfc.nasa.gov/docs/software/xstar/xstar.html.

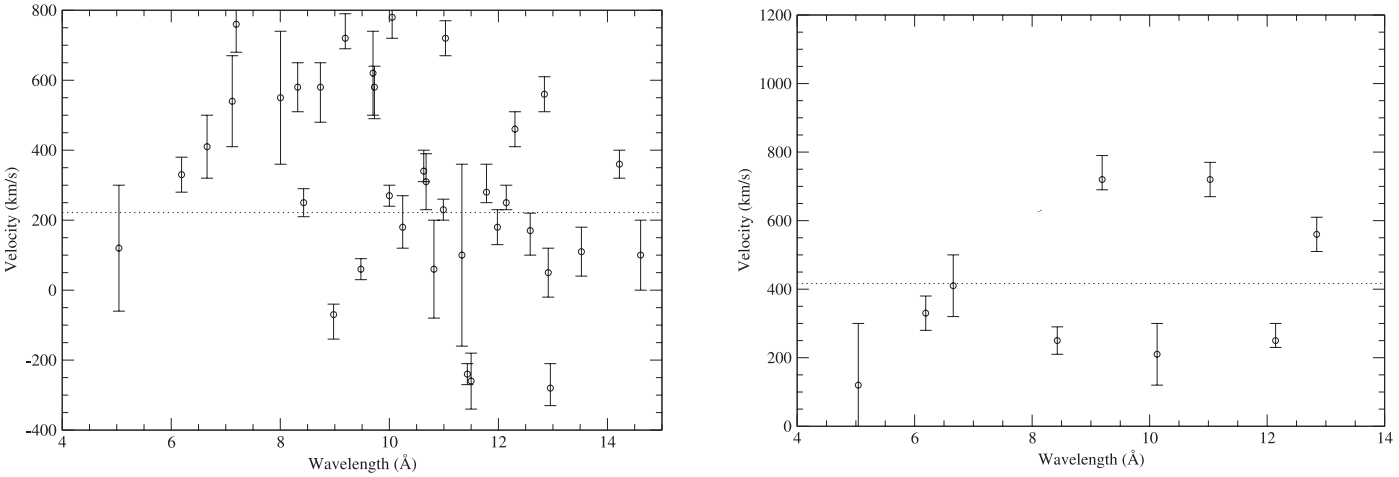

FIG. 6.—Inferred Doppler shift of the selected absorption lines. *Left*, All the lines with a significance above 5 σ; *Right*, only the lines that were used by Marshall et al. (2001). The dotted line shows the average Doppler velocity in both cases.

5 σ, we looked for a systematic red- or blueshift of the lines, following up on the reported redshift of the lines by Marshall et al. (2001) based on data taken in the low-hard state. The results are summarized in Figure 6 (*left*). In this case, although the lines are still systematically redshifted on average, there is not an obvious single-velocity solution. Interestingly, if we limit the results only to those lines that were used by Marshall et al. (2001), as shown in the right panel of Figure 6, we would arrive at an average velocity that is very close to what Marshall et al. reported, although the scatter of data points is much larger in our case. On the other hand, our observation spans binary orbital phases from 0.85 to 0.92, according to the most updated ephemeris (Brocksopp et al. 1999b), while that of Marshall et al. covers a phase range of 0.83–0.86. If the redshift of the lines is related

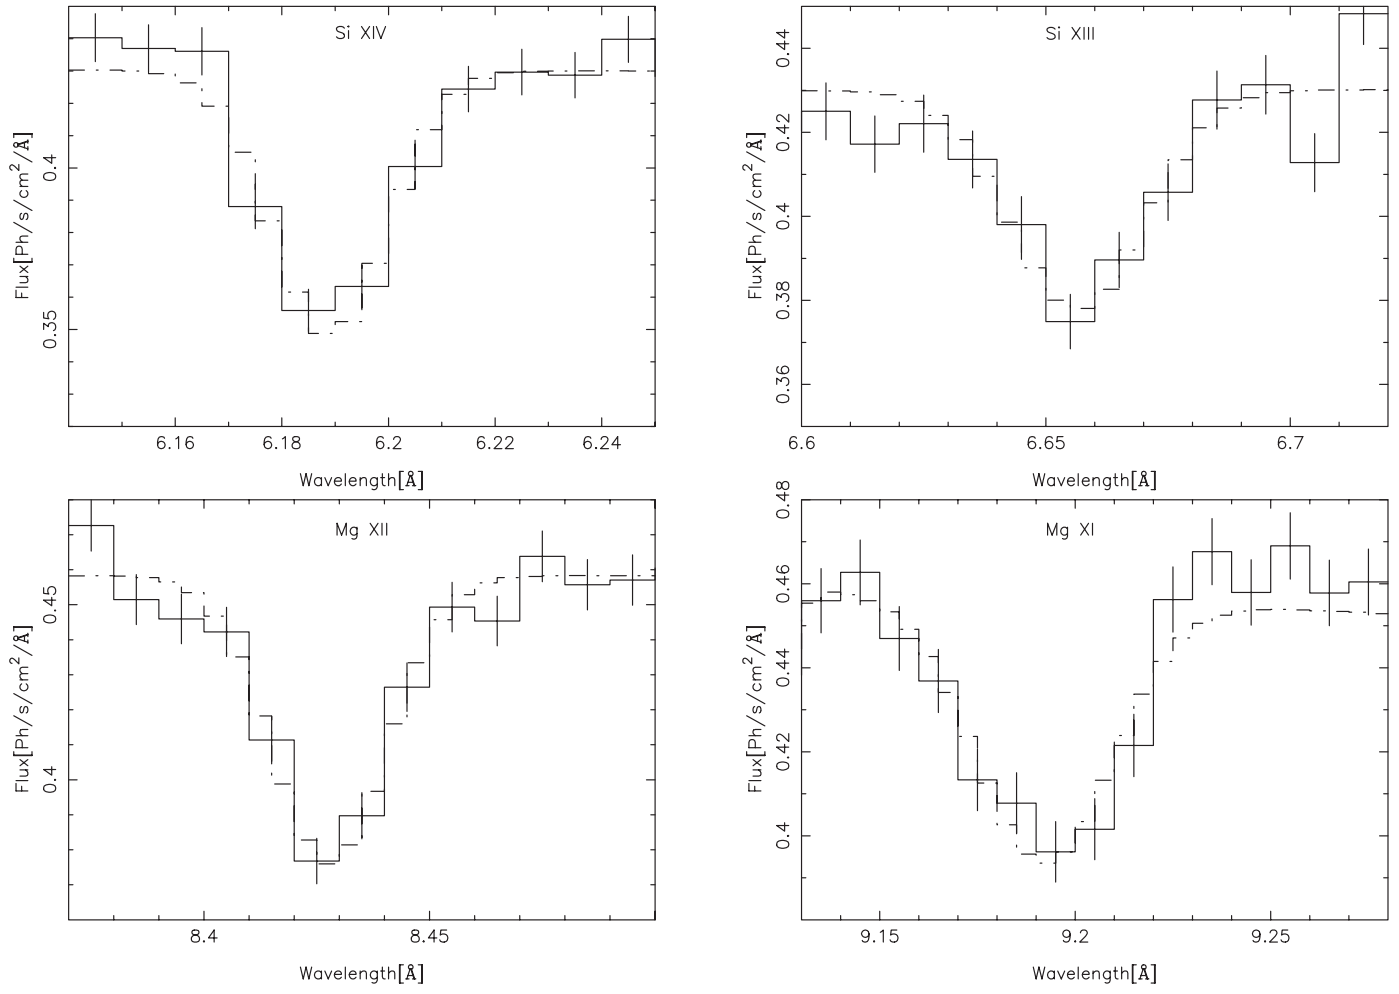

FIG. 7.—Profiles of the selected absorption lines. In each case, the dot-dashed histogram shows a fit to the profile with a Gaussian function.

to the focused-wind scenario advocated by Miller et al. (2005), we ought to see a larger (by about 30%) redshift. Given the large uncertainties, as well as the possibility that the wind geometry might be different for different states, it is difficult to draw any definitive conclusions.

Feng et al. (2003) reported the detection of a number of absorption lines of asymmetric profile, when Cyg X-1 was in the high-soft state, which they interpreted as evidence for inflows. The same lines are also present in our data during period I and are, in fact, much stronger (except for S XVI, as noted in § 3.2). Figure 7 shows an expanded view of the Si and Mg lines, which are the strongest in the group. As is apparent from the figure, the line profile can be fitted fairly well by a Gaussian function in all cases. Therefore, the lines show no apparent asymmetry here. This also seems to be the case for the S and Fe lines, although the statistics of the data are not as good. Taken together, our results and those of Feng et al. imply that the phenomenon is either unique to the high-soft state (in which Feng et al. made the observation) or intermittent in nature. We should also note that the Feng et al. observation was carried out around the superior conjunction (i.e., zero orbital phase), where absorption due to the wind is expected to be the strongest (e.g., Wen et al. 1999). It is not clear, however, how such additional absorption would lead to an asymmetry in the profile of lines.

No emission lines are apparent in our data. Evidence for weak emission lines has been presented (Schulz et al. 2002; Miller et al. 2005), but the significance is marginal in all cases. On the other hand, several absorption edges are easily detected in our data (see Figs. 3 and 4), as first reported and studied in detail by Schulz et al. (2002). The edges can almost certainly be attributed to the interstellar absorption.

We thank Harvey Tananbaum for approving this DDT observation, Norbert Schulz and Herman Marshall for helpful discussion on the pros and cons of various observing configurations, John Houck for help with the use of ISIS and Tim Kallman for help on using XSTAR, and David Huenemoerder for looking into issues related to the *Chandra* data products. We acknowledge the use of the curve-of-growth analysis script that Taro Kotani has made publicly available. We also thank the anonymous referee for a number of useful comments that led to significant improvement of the manuscript. Support for this work was provided in part by NASA through *Chandra* award DD1-2011X issued by the *Chandra X-Ray Observatory* Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of NASA under contract NAS8-03060, and through LTSA grant NAG5-9998.
