Abstract Abstract

Itz this paper we address rlze proble17z of e/zsuri/zg tlze cor-In this paper we address the problem ofensuring the correctness of query results returned by an untrusted private database. The database okvtzs rlze data and /nay nzodi' it database. The database owns the data and may modify it at any rime. The querier is allo~ved to execute queries over at any time. The querier is allowed to execute queries over this database; however it /nay /lot Ieanz a/z).thing nzore than this database; however it may not learn anything more than the result of these legal queries. The querier does not nec-the result of these legal queries. The querier does not necessarily trust the database and would like rlze owtier to fur-essarily trust the database and would like the owner to furtzislz proof that the data has nor been tnodijed in response nish proof that the data has not been modified in response to recent events suclz as tlze submission of the query We to recent events such as the submission of the query. We develop two metrics that capture rlze correctness of query develop two metrics that capture the correctness of query answers and propose a range of solutions that provide a answers and propose a range of solutions that provide a trade-off between rlze degree of exposure of private data, trade-off between the degree of exposure of private data, and the overhead of generation and verijcation of tlze proof: and the overhead ofgeneration and verification ofthe proof Our proposed solutio/zs are rested rlzrouglz i/npleme/ztation Our proposed solutions are tested through implementation using PostgreSQL. Llsing PostgreSQL.

1 Introduction 1 Introduction

Consider the case of the food supply chain which is made Consider the case ofthe food supply chain which is made up of multiple entities: farms, processing plants, distribu-up of multiple entities: farms, processing plants, distribution centers, warehouses, and retailers. These entities are tion centers, warehouses, and retailers. These entities are typically independent, each with its own database that keeps typically independent, each with its own database that keeps track of its operations. Each entity would like to prevent track of its operations. Each entity would like to prevent other entities from learning the details of its operations as other entities from learning the details of its operations as this may yield an advantage to a competitor. However, there this may yield an advantage to a competitor. However, there are instances where it is necessary to provide access to some are instances where it is necessary to provide access to some of this private data in order to enhance public safety, and of this private data in order to enhance public safety, and comply with regulations. For example, if a packet of beef sold at a given store is found to be contaminated, it is necessary to recall all other packages that may also be infected. essary to recall all other packages that may also be infected. This entails searching through the private databases of var-This entails searching through the private databases of ious entities in the supply chain, beginning with the retailer ious entities in the supply chain, beginning with the retailer that sold the package that has been found to be contami-that sold the package that has been found to be contaminated, and working backwards (i.e. to the distributors, pack-nated, and working backwards (i.e. to the distributors, packagers, etc.) to locate the source of the problem and then agers, etc.) to locate the source of the problem and then

To support such queries, the databases can provide a limited in-support such queries, the databases can provide a limited interface into their databases that can be used either by other terface into their databases that can be used either by other entities in the supply chain. or a federal organization. There entities in the supply chain, or a federal organization. There is however. one major problem: since the databases are un-is however, one major problem: since the databases are der the control of individual organizations, there is no guar-der the control of individual organizations, there is no antee that changes are not made to the database in order to antee that changes are not made to the database in order to produce misleading results. Providing incorrect results can help an organization protect itself or a partner from blame, help an organization protect itself or a partner from blame, and shift the blame to another innocent party. Once again, it and shift the blame to another innocent party. Once again, it is desirable that the external querier be able to obtain proof is desirable that the external querier be able to obtain proof that the results returned by the database do reflect the cor-that the results returned by the database do reflect the rect evaluation of the submitted query over an uncorrupted version of the database. version of the database.

More generally. consider the case where a law enforcing More generally, consider the case where a law enforcing agency (e.g. the FBI) wants to query a corporate database for the purpose of ensuring compliance with regulations. for the purpose of ensuring compliance with regulations. The entity owning the data may be very concerned about The entity owning the data may be very concerned about privacy and not be willing to reveal its entire database to privacy and not be willing to reveal its entire database to this agency. At the same time, there is an issue of trust. this agency. At the same time, there is an issue of trust. The federal agency cannot blindly trust the corporation to The federal agency cannot blindly trust the corporation to provide uncorrupted results, and would like to receive some provide uncorrupted results, and would like to receive some proof from the database (which the agency cannot contest) proof from the database (which the agency cannot contest) that it has provided the correct result. This proof must han-that it has provided the correct result. This proof must handle the case that the database owner could have changed the dle the case that the database owner could have changed the data once the investigation has begun to mislead the agency.

A similar problem exists with virtually any situation A similar problem exists with virtually any situation where mutually distrusting entities need to exchange some where mutually distrusting entities need to exchange some data while preserving the privacy of the rest of the database. data while preserving the privacy of the rest of the database. Emerging and recent regulations such as Sarbanes Oxley, Emerging and recent regulations such as Sarbanes Oxley, and CFR 22 part 11 also impose constraints on the handling of data owned by corporations. Solutions that can provide of data owned by corporations. Solutions that can provide

guarantees of correctness of queries over these databases guarantees of correctness of queries over these databases without exposing the entire contents of the database are without exposing the entire contents of the database are highly desirable. In all these examples, it is in the interest highly desirable. In all these examples, it is in the interest of the database owner to share data with business partners of the database owner to share data with business partners or regulatory agencies. or regulatory agencies.

Thus in practice, there is a strong need for providing Thus in practice, there is a strong need for providing guarantees of correctness of query results executed over a guarantees of correctness of query results executed over a private database not under the control of the querier. One private database not under the control of the querier. One possible solution to this problem is to involve an external possible solution to this problem is to involve an external entity that is trusted (willingly or by law), e.g. the USDA in entity that is trusted (willingly or by law), e.g. the USDA in the food supply example. Each database owner then sends the food supply example. Each database owner then sends a copy of their database (and updates) to this *trusted third* a copy of their database (and updates) to this *trusted third part):* which can verify that the queries are executed cor-*party* which can verify that the queries are executed correctly. In fact, it could execute the queries itself. There are rectly. In fact, it could execute the queries itself. There are several problems with this solution: 1) This is a very ex-several problems with this solution: I) This is a very expensive solution with respect to the voluine of traffic to the pensive solution with respect to the volume of traffic to the third party and also the requirements of storage at the third third party and also the requirements of storage at the third party; 2) this third pasty is a potential weakness in the sys-party; 2) this third party is a potential weakness in the system - if it is compromised, then too much private data may tem - if it is compromised, then too much private data may be compromised; 3) the trusted party is now liable for the be compromised; 3) the trusted party is now liable for the privacy of the data - it may be subjected to lawsuits claim-privacy of the data - it may be subjected to lawsuits claiming that it has leaked (willingly or unwillingly) private data ing that it has leaked (willingly or unwillingly) private data of one organization to another; and 4) such solutions would of one organization to another; and 4) such solutions would be resisted by privacy advocates since there is too much of be resisted by privacy advocates since there is too much of a "Big Brother" flavor. a "Big Brother" flavor.

To the best of our knowledge, this problem has not been To the best of our knowledge, this problem has not been addressed earlier. Existing solutions for tamper proofing au-addressed earlier. Existing solutions for tamper proofing audit trails [15], or privacy-preserving database access [9, 11, dit trails [15], or privacy-preserving database access [9, I], and authentic third-party data publication [6, 4, I 11 are not and authentic third-party data publication [6, 4, ll] are not applicable in this domain as discussed in the related work applicable in this domain as discussed in the related work section. In this paper we propose scalable solutions for section. In this paper we propose scalable solutions for the privacy-preserving query result verification problem and the privacy-preserving query result verification problem and develop a number of solutions that provide a tradeoff be-develop a number of solutions that provide a tradeoff between the overhead for the owner, the efficiency of the veri-tween the overhead for the owner, the efficiency of the verification, and the degree of exposure of the owner's database fication, and the degree of exposure of the owner's database in order to prove the correctness of a query. It should be pointed, however, out that our solution is directly applicable pointed, however, out that our solution is directly applicable to the authentic third party data publication and the tamper to the authentic third party data publication and the tamper proofing of audit trail problems too (with no modification proofing of audit trail problems too (with no modification whatsoever) with the added advantage that we do not need whatsoever) with the added advantage that we do not need to trust the owner of these databases. to trust the owner of these databases.

The specific problem considered in this paper is as fol-The specific problem considered in this paper is as follows. We have two entities - the database owner (Bob) and lows. We have two entities - the database owner (Bob) and the querier (Alice). The two entities do not entirely trust the querier (Alice). The two entities do not entirely trust each other. Bob allows Alice to execute certain queries over each other. Bob allows Alice to certain queries over his private database. He is willing to reveal as little infor-his private database. He is willing to reveal as little information as possible to Alice, apart from the results of the query. Alice, on the other hand, is not necessarily confident query. Alice, on the other hand, is not necessarily confident of the results she receives and may want a *guaratltee* from of the results she receives and may want a *guarantee* from Bob that he has returned the correct results to Alice, without Bob that he has returned the correct results to Alice, without modifying the database (e.g. *afrer* receiving Alice's query). modifying the database (e.g. *after* receiving Alice's query). Figure **1** shows the high-level model of the problem with Figure I shows the high-level model of the problem with the possibility of a trusted third party. Alice can ask Bob to the possibility of a trusted third party. Alice can ask Bob to commit to his database (while preserving its privacy) before commit to his database (while preserving its privacy) before issuing a query. Alternatively, Bob can periodically commit issuing a query. Alternatively, Bob can periodically commit the database. In this paper, the notion of "commit" is that the database. In this paper, the notion of "commit" is that Bob ensures that he can prove the authenticity of these data Bob ensures that he can prove the authenticity of these data at a later point in time. The important parameters of the at a later point in time. The important parameters of the problem are: 1) providing a guarantee for correctness; 2) problem are: I) providing a guarantee for correctness; 2) the overhead on Bob and Alice; and 3) the degree of expo-the overhead on Bob and Alice; and 3) the degree of exposure of Bob's data other than the query results. sure of Bob's data other than the query results.

Figure 1. Interaction between the entities. Figure 1. Interaction between the entities.

In its full generality this problem is very hard to solve. In its full generality this problem is very hard to solve. Note that the database owner can legitimately modify any Note that the database owner can legitimately modify any value in its database (e.g. the number of cans of soup sold value in its database (e.g. the number of cans of soup sold today). Thus we would need some means of distinguishing today). Thus we would need some means of distinguishing valid modifications from invalid ones. This problem is very valid modifications from invalid ones. This problem is very hard to solve, and we believe that it is impractical to provide hard to solve, and we believe that it is impractical to provide guarantees about dynamic attributes - i.e. those that change guarantees about dynamic attributes - i.e. those that change over time as part of the operations of the database. We therefore begin by making the following assumptions to limit the fore begin by making the following assumptions to limit the scope of the problem. We assume that guarantees can only scope of the problem. We assume that guarantees can only be provided for data that is not modified after a given point be provided for data that is not modified after a given point in time (e.g. the number of cans of soup sold yesterday or in time (e.g. the number of cans of soup sold yesterday or earlier.). Bob *freezes* the values of certain data periodically earlier.). Bob *freezes* the values of certain data periodically (e.g. daily or every few hours), after which no modification (e.g. daily or every few hours), after which no modification or deletion of these data is allowed. (To be more precise, or deletion of these data is allowed. (To be more precise, modifications are allowed, but their authenticity cannot be modifications are allowed, but their authenticity cannot be guaranteed.) guaranteed.)

The owner generates a proof that it has frozen the The owner generates a proof that it has frozen the database at regular intervals and ships that proof to an ex-database at regular intervals and ships that proof to an external entity. This could be Alice, or a third party (note that ternal entity. This could be Alice, or a third party (note that we do not need to fully trust this third party). The only re-we do not need to fully trust this third party). The only requirement from the third party (if it is used) is that it does quirement from the third party (if it is used) is that it does not modify the proof. The inclusion of the third party is not modify the proof. The inclusion of the third party is only a minor issue and does not impact any of the details of our solution. Consequently, throughout this paper we will assume that Alice receives the proof. The contributions of assume that Alice receives the proof. 3 Assumptions and Model 3 **Assumptions and Model**

In this section, we describe the assumptions and trust In this section, we describe the assumptions and trust model for the entities involved in the protocol. model for the entities involved in the protocol.

3.1 Querier (Alice) 3.1 Querier (Alice)

The database is located in a remote location over which The database is located in a remote location over which Alice has no control. The database determines what types Alice has no control. The database determines what types of queries are allowed to be executed. In order to prove of queries are allowed to be executed. In order to prove that the results of allowed queries are correct, the database that the results of allowed queries are correct, the database periodically commits ("freezes") its current state. Subse-periodically commits ("freezes") its current state. Subsequent queries must be guaranteed to return results computed quent queries must be guaranteed to return results computed over this commit state. Any change to the committed values should be detected. Alice may demand proof of correctness should be detected. Alice may demand proof of correctness of a given result and also demand that data be committed of a given result and also demand that data be committed before submitting a query. Correctness of results can only before submitting a query. Correctness of results can only be guaranteed over committed data. be guaranteed over committed data.

In case of such an update, Alice will either detect this In case of such an update, Alice will either detect this modification or Bob should send Alice the value of the tu-modification or Bob should send Alice the value of the tuple at the time it was frozen. The application semantics ple at the time it was frozen. The application semantics determines which of the above action is more appropriate. determines which of the above action is more appropriate. In either case, this does not restrict the applicability of the In either case, this does not restrict the applicability of the results of this paper. results of this paper.

3.2 Database owner (Bob) 3.2 Database owner (Bob)

The database owner controls the private database. He The database owner controls the private database. He has unconditional read and write access to the database. He has unconditional read and write access to the database. He can intercept all the queries posed to the database and their can intercept all the queries posed to the database and their results: and may even modify the results. In order to prove results, and may even modify the results. In order to prove the correctness of the query results, Bob explicitly generates a proof by freezing the data. Note that since Alice does ates a proof by freezing the data. Note that since Alice does not trust Bob, some proof of the freezing must be shipped not trust Bob, some proof of the freezing must be shipped outside of the database where it cannot be modified by Bob. outside of the database where it cannot be modified by Bob. This can be achieved by either sending some information to This can be achieved by either sending some information to Alice, to a semi-trusted third party, or can be authenticated Alice, to a semi-trusted third party, or can be authenticated by an independent authentication authority. We assume that by an independent authentication authority. We assume that whatever data is frozen by Bob is correct. In practical set-whatever data is frozen by Bob is correct. In practical settings, this is the same as recording entries in an accounts tings, this is the same as recording entries in an accounts the entries of the entries can be audited, the owner is discouraged from recording incorrect data. similarly, for the couraged from recording incorrect data. Similarly, for the current problem, there needs to be in place a mechanism current problem, there needs to be in place a mechanism

that enables a random audit of frozen data in order to en-that enables a random audit of frozen data in order to ensure that Bob does not freeze incorrect data. Once a data item is frozen, the protocol should not allow him to mod-item is frozen, the protocol should not allow him to ify it - i.e. Bob's hands should be tied with respect to the ify it - i.e. Bob's hands should be tied with respect to the frozen data. This is a reasonable assumption given that the frozen data. This is a reasonable assumption given that the event which causes Bob to become malicious and skew the event which causes Bob to become malicious and skew the results to his favor does not happen before Bob generates results to his favor does not happen before Bob generates and sends the proof. Nevertheless, we do not trust Bob to follow the algorithm correctly. He may try to find loopholes in the algorithm to generate a proof that does not tie his hands completely (e.g. as discussed in Appendix A, instead hands completely (e.g. as discussed in Appendix A, instead of freezing a tuple to one value, Bob may try to freeze it in such a way that allows him to report two or more possible such a way that allows him to report two or more possible values for that tuple). values for that tuple).

There is no restriction on how the query results can be There is no restriction on how the query results can be modified. Further, Bob is concerned about the privacy of modified. Further, Bob is concerned about the privacy of the database. He wishes to reveal only a minimal amount of the database. He wishes to reveal only a minimal amount of information to Alice, in addition to the query results. information to Alice, in addition to the query results.

3.3 Definition of Correctness 3.3 Definition of Correctness

There are two aspects of correctness of query results. There are two aspects of correctness of query results. We now present two requirements for the correctness of We now present two requirements for the conectness of query results returned by a private database. Without loss query results returned by a private database. Without loss of generality, we can denote the result tuples of a SPJ query (queries involving only select, projects and joins) as: (queries involving only select, projects and joins) as:

$$
R_i = R_{i_1}^{T_1} \| R_{i_2}^{T_2} \dots \| R_{i_q}^{T_q}
$$

where \parallel denotes concatenation, R_i is the i^{th} tuple of the result and $R_{i,j}^{T_j}$ refers to the value of projected attributes of tuple i_j of table T_j . We divide the correctness requirements into α - and β -correctness as defined below. result and $R_{i,j}^{+j}$ refers to the value of projected attributes of tuple i_j of table T_j . We divide the correctness requirements

 α -correctness This refers to the *correctness of the result values,* i.e. the validity of the tuple values returned by the *values,* i.e. the validity of the tuple values returned by the query. Formally, this implies that the values returned, $R_i^{T_j}$, must match values that were frozen when the proof was gen-must match values that were frozen when the proof was erated. erated.

 β -correctness This refers to the *correctness of query ex*ecution. It implies that the joins and selections were performed correctly and the ith tuple of the result should in fact consist of (subset of) data from tuples $i_1, i_2, \ldots i_q$ of tables T_1, T_2, \ldots, T_q respectively. This definition also checks for absence of valid tuples from the result set. absence of valid tuples from the result set.

To understand β -correctness intuitively, it is helpful to picture the database table as collection of tuple ids only. picture the database table as collection of tuple ids only. E.g. for a selection query β -correctness only tests whether $E.g.$ for a selection query ρ -correctness only tests whether the correct tuple ids are part of the result $-$ it does not check whether the tuple data corresponding to these tuple ids is unmodified. In case of joins, it checks that correct pairs unmodified. In case of joins, it checks that correct pairs

Figure 2. Example tables for Query Correct-Figure 2. Example tables for Query Correctness. ness.

of tuple ids from two tables are in the result. While β correctness does not check the tuple contents, α -correctness ties the tuple id to the contents stored in the tuple, and en-ties the tuple id to the contents stored in the tuple, and sures that they are not tampered. sures that they are not tampered.

Consider two relations, $R(A, B)$ and $S(A, C, D)$, and the query the query

$$
\pi_{B,C}(\sigma_{S.D=d_1}(R \bowtie_{R.A=S.A} S))
$$

Example instances of the two relations are shown in Fig-Example instances of the two relations are shown in ure 2. The correct result of the query should be the tuples: $\{< b_1, c_1 > , < b_2, c_2 > \}.$ α -correctness requires the database to prove beyond any doubt that the tuples in the database to prove beyond any doubt that the tuples in the result are indeed committed values. For this specific ex-the result are indeed committed values. For this specific ample, this amounts to proving that b_1 and b_2 are part of some frozen tuples in table R (and similarly for c_1 and c_2). β -correctness requires that the selections and joins are correctly performed and all the resulting tuples are returned. For example, if the database only returns: $\{ < b_1, c_1 > \}$ (an incomplete result), or $\{ < b_1, c_1 > , < b_2, c_2 > , < b_1, c_3 > \}$ (incorrect selection) or $\{< b_1, c_1>, < b_2, c_2>, < b_1, c_2>$) (incorrect join) then Alice should be able to discover this } (incorrect join) then Alice should be able to discover this inconsistency. Note that all these results are α -correct as the values returned do belong to some tuple in the table. The β con-ectness proof will verify that the tuples containing the conectness proof will verify that the tuples containing the values returned (as certified by α -correctness) should in fact be in the result of the query. be in the result of the query.

These two definitions are independent of each other and These two definitions are independent of each other and together imply the correctness of query results. As de-together imply the correctness of query results. As described later, for some specific cases we may not need the scribed later, for some specific cases we may not need the β -correctness requirement in order to verify the correctness of query results. of query results.

3.4 Query 3.4 Query

The solutions proposed in this paper can guarantee a-The solutions proposed in this paper can guarantee *a*correctness for any arbitrary query over the database. How-correctness for any arbitrary query over the database. ever, for the case of the more challenging β -correctness, we need to limit the types of queries of the form: need to limit the types of queries of the form:

$$
\pi_{p_1, p_2, \ldots, p_m}(\sigma_{s_1 = a_1, s_2 = a_2, \ldots, s_n = a_n} (T_1 \boxtimes T_2 \boxtimes \ldots T_q))
$$

where $p_1, p_2 \ldots p_m, s_1, s_2, \ldots s_n$ are the attributes of the tables T_1, T_2, \ldots, T_q of the database. The joins between the tables are assumed to be *equality* joins. tables are assumed to be *equality* joins.

It should be noted that our approach can also prove cor-It should be noted that our approach can also prove correctness for queries whose results are essentially derived from queries of the type shown above (e.g. aggregate from queries of the type shown above (e.g. aggregate queries) by proving the correctness of the underlying query, queries) by proving the correctness ofthe underlying query, we can show that the derived query was also correctly eval-we can show that the derived query was also correctly evaluated. For example, we can prove correctness for a query uated. For example, we can prove correctness for a query that computes an aggregate over a set of tuples generated that computes an aggregate over a set of tuples generated by a query of the type shown above. This paper employs two standard data security tools: This paper employs two standard data security tools: *strorzg one-way haslz furzctiorzs* [13] and *Merkle Trees* [101. *strong one-way hash functions* [13] and *Merkle Trees [10].* We provide a brief description of these tools before dis-We provide a brief description of these tools before discussing the proposed solutions. cussing the proposed solutions.

4.1 One-Way Hashing 4.1 One-Way Hashing

A one-way hash is a function, h , that takes as input a data item, x and produces as output the'hash of the data data item, *x* and produces as output the' hash of the data item, $y = h(x)$. Important requirements for a one-way hash function are: function are:

- 1. Given a hash value, y, and the details of the hashing 1. Given a hash value, *y,* and the details of the hashing function h, it is very difficult to find x such that $h(x) =$ y . In other words, given the hash of a data item it is hard to work back and determine the data value that hard to work back and determine the data value that generated this hash value. generated this hash value. y. In other words, given the hash of a data item it is
hard to work back and determine the data value that
generated this hash value.
2. The probability that $h(x) = h(y)$ for $x \neq y$ is very
low. i.e., it is very unlikely th
- low. i.e., it is very unlikely that two different values low. i.e., it is very unlikely that two different values will yield the same hash. will yield the same hash. 2. The probability that $h(x) = h(y)$ for $x \neq y$ is very

Therefore, given a hashed value, y, it is virtually impos-Therefore, given a hashed value, *y,* it is virtually impossible to discover any data value that yields y as its hash value. If a value x is known, then it is virtually impossible to generate a second value z such that $h(z) = h(x)$. Thus, given a hash value y, it is possible to determine x such that given a hash value *y,* it is possible to determine *x* such that $y = h(x)$ only if x is already known (or one gets extremely lucky). There are many well-known and commonly used lucky). There are many well-known and commonly used strong one-way hash functions, such as SHA-256. strong one-way hash functions, such as SHA-256.

Another important class of hash functions are *cvpto-*Another important class of hash functions are *crypto* g raphically ${sec}$ ure ${keyed}$ ${hash}$ functions, denoted by h_k . These work in much the same way as a one-way hash func-These work in much the same way as a one-way hash function, but they take as an additional input, a key, k . With such a function, given x it is not possible to determine $h_k(x)$ even if we know the hash function unless the key k is also known.

4.2 Merkle Trees 4.2 Merkle Trees

A Merkle tree [lo] is a binary tree (not necessarily com-A Merkle tree [10] is a binary tree (not necessarily plete) with labeled nodes. The labels are binary strings plete) with labeled nodes. The labels are binary strings of length k. Let $\Phi(n)$ represent the label of node *n*, thus $\Phi(n) \in \{0,1\}^k$. The label for each internal node of the tree, n_{parent} , with children, n_{left} and n_{right} , is derived from the labels of its children using a hash function, *h* as:

$$
\Phi(n_{parent}) = h(\Phi(n_{left}) \parallel \Phi(n_{right}))
$$

The function *h* is a candidate one-way function such as SHA-256. The above equation gives assignment of Φ for internal nodes. For leaf nodes, Φ is usually chosen depending upon the application of merkle trees. For example, Φ for a leaf can be the hash of a small part of a document whose a leaf can be the hash of a small part of a document whose integrity we want to establish. integrity we want to establish.

Figure 3. An example Merkle tree. The black Figure 3. An example Merkle tree. The black nodes form the authentication path of shaded nodes form the authentication path of shaded data block. data block.

Merkle trees are used to establish the authenticity of the Merkle trees are used to establish the authenticity of the leaf node labels. This is achieved by simply publishing the leaf node labels. This is achieved by simply publishing the value of the root's label. Publishing in this context, refers to recording the value in a manner that cannot be modified to recording the value in a manner that cannot be modified later. This can be achieved by printing this value in a news-later. This can be achieved by printing this value in a paper, or using an authentication service. With this pub-paper, or using an authentication service. With this published and unmodifiable value, one can now establish that lished and unmodifiable value, one can now establish that the value for any of the leaf labels has not been modified the value for any of the leaf labels has not been modified after the publication of the root's label. Consider for ex-after the publication of the root's label. Consider for ample, the merkle tree shown in Figure 3. In this example, ample, the merkle tree shown in Figure 3. In this example, the labels for the leaf nodes correspond to the hash values the labels for the leaf nodes correspond to the hash values of data items whose authenticity we would like to establish. of data items whose authenticity we would like to establish. In order to prove that the value of the data item x (shown shaded in the figure) has not been modified, we simply need shaded in the figure) has not been modified, we simply need

to provide the value of x (the hash function for the tree is well known), and the labels of the sibling nodes on the path well known), and the labels of the sibling nodes on the path from x to the root. These nodes are shown as black circles from *x* to the root. These nodes are shown as black circles in the figure. This path is called the *authentication path* for in the figure. This path is called the *authentication path* for x . To verify the claim, one computes the labels of the nodes along the path using the definition of Φ for internal nodes. If the computed label for the root matches the previously If the computed label for the root matches the previously published value then the value of x is authenticated.

To see why this is so, consider what happens if the value To see why this is so, consider what happens if the value of x has indeed been modified. Given the new value of x, of *x* has indeed been modified. Given the new value of *x,* one would have to create labels for each sibling such that af-one would have to create labels for each such that after repeated computations of the parent labels, the final hash ter repeated computations of the parent labels, the final hash value is the same as the one that was generated earlier. By value is the same as the one that was generated earlier. By the very nature of one-way hash functions, this is extremely the very nature of one-way hash functions, this is extremely difficult to do, thus the labels cannot have been modified. difficult to do, thus the labels cannot have been modified.

5 Simple Model Solution 5 **Simple Model Solution**

In this section, we discuss several solutions with vari-In this section, we discuss several solutions with ous degrees of privacy, computational complexity and data bandwidth. For the moment, we assume that the query con-bandwidth. For the moment, we assume the query tains only select operators and we are only verifying the α correctness of the query results in each of these solutions. correctness of the query results in each of these solutions. We will discuss the general case later. For each solution, we We will discuss the general case later. For each solution, we discuss the **Proof of integrity** that must be shipped by Bob discuss the Proof of integrity that must be shipped by Bob whenever he freezes the data, and the **Verification** steps that whenever he freezes the data, and the Verification steps that Alice must carry out in order to establish the authenticity of Alice must carry out in order to establish the authenticity of data in case she suspects foul play. We begin with a very data in case she suspects foul play. We begin with a very simple solution to illustrate the nature of the problem. In simple solution to illustrate the nature of the problem. In the rest of the paper, the term database refers to the part of the rest of the paper, the term database refers to the part of Bob's private database that is frozen. Bob's private database that is frozen.

In all of these solutions, the hash function h is assumed to be public. The hash function implementations normally to be public. The hash function implementations normally take a sequence of bytes as input and returns an output of take a sequence of bytes as input and returns an output of fixed length. Using this, we can define the function h on any chunk of data in the database. For an attribute value: hash is chunk of data in the database. For an attribute value, hash is simply the hash of bytes representing that value. For bigger simply the hash of bytes representing that value. For bigger units like a tuple or (ordered) set of attributes, *h* is defined as hash of concatenation of all the attributes making up that as hash of concatenation of all the attributes making up that tuple or set respectively. tuple or set respectively.

In some solutions we assume that each tuple is identi-In some solutions we assume that each tuple is identified uniquely. This can be achieved by using RIDS. or for fied uniquely. This can be achieved by using RIDs, or for simplicity, generating an explicit ID within the database. simplicity, generating an explicit ID within the database.

Solution 1 Proof of integrity: Bob computes the hash of the entire database and sends it to Alice. the entire database and sends it to Alice.

Verification: If challenged by Alice to prove the authenticity of the results of a query, Bob ships the entire contents of ity of the results of a query, Bob ships the entire contents of the database to her. Alice can easily i) verify that the result the database to her. Alice can easily i) verify that the result values are indeed part of this database; and ii) compute the values are indeed part of this database; and ii) compute the hash of this database and verify if the overall hash match the hash of this database and verify if the overall hash match the earlier proof. If these two values match, then Bob must have sent the same database that was used to generate the earlier proof (given the difficulty of finding two numbers that hash proof (given the difficulty of finding two numbers that hash to the same value) and has not modified it since. to the same value) and has not modified it since.

This approach has the advantage that the database owner This approach has the advantage that the database owner needs to send only one number (the hash value) to Alice. needs to send only one number (the hash value) to Alice. However, this is obviously a very bad solution since it vi-However, this is obviously a very bad solution since it olates the privacy of Bob's database as he has to reveal the olates the privacy of Bob's database as he has to reveal the entire database when challenged. The bandwidth required entire database when challenged. The bandwidth required for verification is also huge as the entire database needs to for verification is also huge as the entire database needs to be shipped for verification. be shipped for verification.

Solution 2 Proof of integrity: We consider a strong hash function *h* such as SHA-256. For each tuple r_i in the database, Bob generates $h_i = h(r_i)$ and ships (i, h_i) $\forall i$ to Alice. to Alice.

Verification: As the result of a query, Alice gets back (i, r_i) for i in the result set. She can easily hash the result tuples and verify their integrity. In other words, no extra data is and verify their integrity. In other words, no extra data is needed for Alice to verify a result. needed for Alice to verify a result.

The *i* used in this solution can be something which uniquely identifies a tuple in a database table such as RID. uniquely identifies a tuple in a database table such as RID. We can use other approaches which do not use RIDs such as sending the individual hashes in sorted order of hash value, sending the individual hashes in sorted order of hash value, but using RIDS makes the exposition easier. This approach but using RIDs makes the exposition easier. This approach respects the privacy of Bob's database. There is no com-respects the privacy of Bob's database. There is no munication between Bob and Alice during the verification munication between Bob and Alice during the verification phase as she has all the information needed to verify the phase as she has all the information needed to verify the results. This approach can very easily be implemented by results. This approach can very easily be implemented by maintaining a separate field for the hash along with each tu-maintaining a separate field for the hash along with each tuple. The hash is updated whenever a tuple is inserted or ple. The hash is updated whenever a tuple is inserted or modified. Although this increases privacy, it is not very modified. Although this increases privacy, it is not very practical as the size of the proof is proportional to the size practical as the size of the proof is proportional to the size of database. The size of the proof, rather than the size of of database. The size of the proof, rather than the size of the verification, is the major concern as verification may be rare (only when challenged by the querier) as compared to sending the proof of integrity (which may be periodic). sending the proof of integrity (which may be periodic).

Solution 3 Proof of integrity: Let the tuples to be frozen be r_1, r_2, \ldots, r_n . Bob computes the hash of individual tuples $r_1 \ldots r_n$ with hash function *h* to generate $a_1 \ldots a_n$. where $a_i = h(r_i)$. Next, he computes the hash of $a_1 \ldots a_n$ to generate the final proof which he ships to the querier. to generate the final proof which he ships to the querier. Thus the proof is $h(h(r_1)||h(r_2)||...||h(r_n))$.

Verification: Let the result set S be set of all tuple numbers Verification: Let the result set *S* be set of all tuple numbers returned by the query. i.e., the result of the query is a set $\{(j, s_j)\}\; j \in S$. In order to verify this result, Alice asks Bob for (i, a_i) , $\forall i \notin S$. She computes the hash of each result $b_j = h(s_j)$, $j \in S$. Finally, she computes the hash over b_j and a_j hash values received from Bob. I.e. Alice computes: $h(c_1||c_2|| \dots ||c_n)$ where $c_i = b_i$ if $i \in S$, and $c_i = a_i$, otherwise. If this overall hash value equals the proof sent earlier by Bob, then Alice is convinced that the proof earlier by Bob, then Alice is convinced that the result values were indeed part of the frozen database. result values were indeed part of the frozen database.

As in the previous approach, this approach also respects As in the previous approach, this approach also respects the privacy of the database. But now, the proof size is reduced to just one number (the final hash) at the cost of a duced to just one number (the final hash) at the cost of a greatly increased verification size. This overhead associated greatly increased verification size. This overhead associated with hashing is similar to that in the previous approach. As-with hashing is similar to that in the previous approach. Assuming the result set is small, the size of the verification is proportional to the size of the database. Unless verification proportional to the size of the database. Unless verification phases are rare and bandwidth for verification is not a con-phases are rare and bandwidth for verification is not a concern, this approach is not practical. However, this approach cern, this approach is not practical. However, this approach may be useful in situations in which the result set is large. may be useful in situations in which the result set is large.

Solution 4 Proof of integrity: Solution 4 Proof of integrity:

This approach uses merkle trees to reduce the size of the This approach uses merkle trees to reduce the size of the verification from $O(N)$ to $O(\log N)$, where N is the size of the database. The database owner computes a merkle tree as described in Section 4. The definition of merkle trees as described in Section 4. The definition of merkle trees gives the assignment of Φ for internal nodes. For leaf node \overline{l}_i , $\Phi(l_i) = h(r_i)$, where r_i is the *i*th tuple in the database. Bob sends $\Phi(root)$ as proof of integrity to Alice.

Verification: For verification, Bob sends authentication Verification: For verification, Bob sends authentication path for result tuples that need to be verified to Alice. The path for result tuples that need to be verified to Alice. The length of such a path is equal to the height of tree which length of such a path is equal to the height of tree which is proportional to $O(\log N)$. Alice computes the hash over the result that she has received and the hash values along the authentication path supplied by Bob. If the overall hash generated by Alice using the result values and the authenti-generated by Alice using the result values and the cation path hashes matches the proof sent earlier, all result cation path hashes matches the proof sent earlier, all result tuples are authenticated. tuples are authenticated.

This approach preserves database privacy as it reveals This approach preserves database privacy as it reveals only the hashes of tuples that are not part of the result. Thus Alice learns nothing about the values of the other data items. Alice learns nothing about the values ofthe other data items. While the size of the proof is the same as in Solution 3 (one While the size of the proof is the same as in Solution 3 (one single hash), the size of the verification is greatly reduced single hash), the size of the verification is greatly reduced from $O(N)$ to $O(\log N)$. The computational complexity is proportional to number of nodes (both leaf and internal) of proportional to number of nodes (both leaf and internal) of the merkle tree. For a binary tree with N leaves, the total the merkle tree. For a binary tree with N leaves, the total number of nodes is $2N - 1$. Therefore, the computational complexity of this approach is only twice as much as the complexity of this approach is only twice as much as the previous approach. previous approach.

Table I summarizes the various solutions and their prop-Table I summarizes the various solutions and their properties. These solutions were developed for ensuring α correctness only with the assumption that no projects are correctness only with the assumption that no projects are performed. However, as explained below, they can be performed. However, as explained below, they can be extended to more general queries and also to prove β correctness (with small modifications).

5.1 a-Correctness of General Queries 5.1 a-Correctness of General Queries

As discussed above, Solution 4 is superior to the others As discussed above, Solution 4 is superior to the others for verifying the α -correctness assuming that the number of tuples in the result set is small. We next describe this ap-tuples in the result set is small. We next describe this approach in detail for verifying the α -correctness in the general case. eral case.

5.1.1 **Granularity of Hashing** 5.1.1 Granularity of Hashing

In all of the above solutions, we have assumed that the tu-In all of the above solutions, we have assumed that the tuples are hashed at the granularity level of individual tuples. ples are hashed at the granularity level of individual tuples. This granularity determines how much information must be This granularity determines how much information must be reveaIed during verification. Consider a table has attributes revealed during verification. Consider a table has attributes $A = \{a_1, a_2, \ldots, a_n\}$ and the query returns $B \subset A$ as the result. During verification, for each result tuple, the the result. During verification, for each result tuple, the the result. During verification, for each result tuple, the values of all $A - B$ attributes must be revealed for the querier to verify the α -correctness of the results (by tracing the authentication path). This increases the data band-ing the authentication path). This increases the data bandwidth required for verification and reduces the privacy of width required for verification and reduces the privacy of the database. the database.

To overcome this problem, the granularity of hashing To overcome this problem, the granularity of hashing can be adjusted so that no additional information is revealed during verification. For the above example query, vealed during verification. For the above example query, vealed during verification. For the above example query,
Bob would hash *B* and $A - B$ separately, i.e. Φ (tuple) = Bob would hash B and $A - B$ separately, i.e. Φ (tuple) = $hash(\Phi(B) \parallel \Phi(A - B))$, where $\Phi(S) = h(S)$ for any $S \subset A$. Now, in order to verify a result tuple which has $S \subseteq A$. Now, in order to verity a result tuple which has only *R* attributes, we do not need to reveal $A - B$ attributes $-$ only the hash of the $A - B$ attributes for that tuple is sent to Alice. This enables the database to mask private attributes that are not accessible to Alice or not part of the result. that are not accessible to Alice or not part of the result.

Working with a finer granularity of hashing, we can Working with a finer granularity of hashing, we can avoid violating the privacy of the database when the query avoid violating the privacy of the database when the query result does not include all attributes of the table. However, result does not include all attributes of the table. However, at the same time, the finer granularity has a price associated at the same time, the finer granularity has a price associated with it. A finer granularity of hashing will increase the au-with it. A finer granularity of hashing will increase the authentication data needed for verifying a data item. It should thentication data needed for verifying a data item. It should be noted that switching to a much finer granularity will in-be noted that switching to a much finer granularity will increase the time needed to generate the proof and verify the crease the time needed to generate the proof and verify the results as described in Section 7. results as described in Section 7.

Consequently, a judicious choice of the granularity for Consequently, a judicious choice of the granularity for hashing needs to be made in order to balance the cost of hashing needs to be made in order to balance the cost of generating a proof and the degree of exposure of private data during verification. Given a set of queries that will be data during verification. Given a set of queries that will be allowed to execute over a relation, let $R_i \subseteq T$ be the set of attributes queried by query **i.** The granularity of hashing for attributes queried by query i. The granularity of hashing for Relation $T, G_T = \{A_1, A_2, \ldots, A_m\}, A_j \subseteq T$, is decided such that such that

- 1. $A_i \bigcap A_j = \phi, \forall i, j \in \{1, 2, \ldots m\}, i \neq j$; and
- 2. $\forall i, \exists J_i \subseteq \{1, 2, \ldots m\}$, such that $R_i = \bigcup_{j \in J_i} A_j$

The first condition ensures that we do not include an at-The first condition ensures that we do not include an attribute in more than one hash. which would incur costs in tribute in more than one hash, which would incur costs in terms of efficiency and space. The second condition im-terms of efficiency and space. The second condition implies that we always have a subset of hashed attributes that plies that we always have a subset of hashed attributes that will cover all the attributes projected by any query. This will cover all the attributes projected by any query. This avoids the need to reveal any more information than what is avoids the need to reveal any more information than what is already revealed during the verification phase. already revealed during the verification phase.

Solution 5 α We now present the final solution for proving α -correctness for arbitrary SPJ queries, and also address an

important attack for domains with small cardinality. With important attack for domains with small cardinality. With these definitions, we can redefine $\Phi(l_i)$ for a leaf node l_i as

$$
\Phi(l_i) = hash(tuple\ id\|\Phi(A_1^i)\|\Phi(A_2^i)\|\dots\|\Phi(A_m^i))
$$

where A_i^i refers to the value of attribute(s) A_j for i^{th} tuple and $\Phi(\vec{A}_i^i) = hash(A_i^i)$. Including *tuple id*, the unique identifier for a tuple, in $\Phi(l_i)$ (and thus in the authentication path of all attributes) allows the querier to verify if the data path of all attributes) allows the querier to verify if the data for which α -correctness is being tested, does indeed belong to tuples which are verified by the β -correctness verification algorithm as belonging to the result set. It should be noted algorithm as belonging to the result set. It should be noted that in the absence of knowledge about which subsets of attributes are likely to be queried, we can treat each attribute attributes are likely to be queried, we can treat each attribute as one of the A_i sets. This allows us to provide maximal privacy for all the attributes. privacy for all the attributes.

With this definition, the leaf nodes of the merkle tree are With this definition, the leaf nodes of the merkle tree are no longer labeled $h(r_i)$ corresponding to tuple r_i . Instead, the hash values of the various sets of attributes values $h(A_i)$ form the new leaf level. The next level up contains one form the new leaf level. The next level up contains one node for each tuple r_i of the database. Its label is the hash of the concatenation of labels for the m leaves of tuple r_i : $h(A_i^i)$, $j = 1...m$ and the tuple-id for r_i . This grouping together of the hashes of attribute of one tuple simplifies the together of the hashes of attribute of one tuple simplifies the implementation and allows Alice to easily verify whether implementation and allows Alice to easily verify whether two attributes reported (by query results) as part of one tuple two attributes reported (by query results) as part of one tuple of the table are in fact part of one tuple and not two different tuples. tuples.

5.1.2 Handling attributes with small domains 5.1.2 Handling attributes with small domains

The security of hash functions depends on the assumption The security of hash functions depends on the assumption that the domain of the hash function is large. If the domain is small (e.g. age) a simple dictionary attack will allow main is small (e.g. age) a simple dictionary attack will allow the querier to deduce the attribute values from their hashes. the querier to deduce the attribute values from their hashes. The querier simply hashes each possible value (e.g. every The querier simply hashes each possible value (e.g. every age from 1 to 120, say) to produce the corresponding hash. age from I to 120, say) to produce the corresponding hash. Comparing these hash values with the hash values of private Comparing these hash values with the hash values of private fields allows the querier to determine the value of the field. fields allows the querier to determine the value of the field. We solve this problem by generating the hash of the data We solve this problem by generating the hash of the data value concatenated with another value not known to Alice. This secret value is called "salt". This secret value is called "salt".

We redefine $\Phi(A_i)$ for attributes with small domain cardinality to be: dinality to be:

$$
\Phi(A_j^i) = hash(A_j^i \| S_{i,j})
$$

$$
S_{i,j} = h_k(table \, id \, ||i||j)
$$

where $S_{i,j}$ is the salt for attribute *j* of tuple *i*, and h_k is a cryptographically secure keyed hash function. The key *k* is cryptographically secure keyed hash function. The key *k* is kept secret by the database owner. kept secret by the database owner.

Figure 4. Hash tree for α -correctness. The **shaded nodes forms the authentication path** shaded nodes forms the authentication path **of data item** A;

The size of the salt $S_{i,j}$ must be large enough to make dictionary attacks computationally very difficult for Alice. dictionary attacks computationally very difficult for Alice. $S_{i,j}$ must be revealed to Alice for verification of A_i^i . Figure 4 shows a hash tree and the complete authentication path for a data item A_j^i . In order to verify an attribute value,

Alice will be given both the value of the data (A_j^i) and the value of the corresponding salt $(S_{i,j})$ used to generate the proof. Since the salt is released for verification, we cannot proof. Since the salt is released for verification, we cannot use a single value for all data items. Managing different salt use a single value for all data items. Managing different salt values for each data item can be quite cumbersome (and values for each data item can be quite cumbersome (and consume storage) for Bob. To avoid both these problems, consume storage) for Bob. To avoid both these problems, we defining the salt such that it can be derived from the we defining the salt such that it can be derived from the value of the data item through a different hash function h_k . Thus Bob can easily "remember" the hash for any data value Thus Bob can easily "remember" the hash for any data value Thus bob can easily remember the hash for any x to be simply $h_k(x)$ – no need to save the salt.

As described in Section 3, the α -correctness of results alone does not establish the correctness of results. In some alone does not establish the correctness of results. In some special cases, however, verifying only the α -correctness suffices. For example, if the total number of tuples that must suffices. For example, if the total number oftuples that must be retuned by a query is known and all join and selection be returned by a query is known and all join and selection attributes are retained in the result, then the correctness of attributes are retained in the result, then the correctness of query results is completely determined by its α -correctness.

Note that we can verify the α -correctness of the results for any general query. The restriction on queries given in for any general query. The restriction on queries given in Section 3 is necessary only for verifying β -correctness.

5.2 Verifying β -correctness

In the previous section, we discussed how we can mod-In the previous section, we discussed how we can modify merkle trees to establish the α -correctness of the results which ensures that all values returned by the query were in-which ensures that all values returned by the query were indeed frozen by the database. In this section we suggest so-deed frozen by the database. In this section we suggest solutions for establishing β -correctness which ensures that all results for a query are sent to the querier. For this, we need to make sure that the query engine performs all the joins to make sure that the query engine performs all the joins and selects correctly. This is challenging because Bob. the and selects correctly. This is challenging because Bob, the database owner, is not willing to reveal the entire database database owner, is not willing to reveal the entire database due to privacy concerns. Merkle trees can be very band-due to privacy concerns. Merkle trees can be very bandwidth efficient for α -correctness as discussed previously, but they cannot be used for β -correctness. This is due to the fact that we need information about the entire database the fact that we need information about the entire database for verifying the β -correctness.

As discussed earlier (Section 3), for β -correctness we will assume that the queries only contain equality joins. We will assume that the queries only contain equality joins. We use a modified version of the hash tree described in Solution use a modified version ofthe hash tree described in Solution 3. First, we need to define the granularity of hashing to 3. First, we need to define the granularity of hashing to prevent violation of privacy similar to what was proposed prevent violation of privacy similar to what was proposed above for α -correctness in Solution 5 α .

Without loss of generality, let us assume that the query Without loss of generality, let us assume that the query is is

$$
q_i = \pi_{P_i}(\sigma_{S_i}(T_{i_1} \bowtie_{J_i} T_{i_2}))
$$

where $P_i \subseteq T_{i_1} \cup T_{i_2}$ are projected attributes, $S_i \subseteq T_{i_1} \cup T_{i_2}$ are selection attributes and $J_i \subseteq T_{i_1}$ (and $J_i \subseteq T_{i_2}$) are join attributes. Note that the selections and joins are both join attributes. Note that the selections and joins are both based on equality (Section 3). To prove the β -correctness of results without revealing any additional information we of results without revealing any additional information we enforce the following conditions on the granularity $G_T =$ ${A_1, A_2, \ldots, A_m}, A_j \subseteq T,$

- 1. $A_i \bigcap A_j = \phi, \forall i, j \in \{1, 2, ..., m\}, i \neq j$; and
- 2. $\forall i, \exists K_i \subseteq \{1, 2, \ldots m\}$ and $\exists L_i \subseteq \{1, 2, \ldots m\}$, such that

$$
J_i = \bigcup_{k \in K_i} A_k; \quad S_i = \bigcup_{l \in L_i} A_l
$$

In other words, we identify maximal; disjoint subsets of at-In other words, we identify maximal, disjoint subsets of attributes of each relation T such that we can obtain each of the sets required for selections and joins over this rela-of the sets required for selections and joins over this relation for every query. Note that we can always satisfy these tion for every query. Note that we can always satisfy these conditions by picking each set A_i consisting of a single attribute. We now propose a solution for β -correctness.

Figure 5. Hash tree for p-correctness **Figure 5. Hash tree for (3-correctness**

Solution 5@ Solution 5(J

The hash tree over one database table for β -correctness is defined as follows: defined as follows:

$$
\Phi(root) = hash(\Phi(l_1) \|\Phi(l_2)\| \dots \|\Phi(l_n))
$$

$$
\Phi(l_i) = hash(tuple\ id \|\Phi(A_1^i) \|\Phi(A_2^i)\| \dots \|\Phi(A_m^i))
$$

$$
\Phi(A_j^i) = hash(A_j^i \|S_{i,j})
$$

$$
S_{i,j} = S_d(A_j^i)
$$

where, $S_d(A_i^i)$ is the digital signature of Bob on value A_j^i with the private key d . The corresponding public key e is known to Alice. As described later, using a simple keyed known to Alice. As described later, using a simple keyed hash as the salt (similar to our solution for α -correctness) is not sufficient to ensure the β correctness. Figure 5 shows the hash tree described above. The nodes l_1, l_2, \ldots, l_n correspond to each tuple of the table. respond to each tuple of the table.

We have included $tuple$ *id* in the definition of $\Phi(l_i)$ similar to the definition of $\Phi(l_i)$ for α -correctness. Keeping this unique identifier along with the tuples in both $(\alpha$ and β) trees helps Alice to verify that the authentication paths provided by Bob for α and β proofs are for the same data item. If we remove *tuple id* from the above definition, it is possible for Bob to fool Alice, by providing an authentica-possible for Bob to fool Alice, by providing an authentication path for one tuple for α -proof verification and path for a different tuple for β -proof verification (possibly having one or more attribute values equal to the first tuple). Without the or more attribute values equal to the first tuple). Without the unique tuple ids, Alice will have no way to verify if the two unique tuple ids, Alice will have no way to verify if the two proofs point to the same tuples. Thus, tuple ids serve to link proofs point to the same tuples. Thus, tuple ids serve to link the two proofs together. the two proofs together.

During the proof sending phase, the database owner, During the proof sending phase, the database owner, Bob, only sends $\Phi(root)$ for each table to Alice. If Alice requests verification after executing a query, Bob sends (for requests verification after executing a query, Bob sends (for all tables involved in the query) $\Phi(A_j^i)$, $\forall i, j$ and $S_{i,j}$ for all the A_j attributes that are involved in a selection.

Alice checks if the value of $\Phi(root)$ sent for each table matches the value calculated by using hash of all $\Phi(A_i^i)$ sent by Bob. If that succeeds, she only needs to prove that the by Bob. If that succeeds, she only needs to prove that the joins and selections are performed correctly by the database to prove β -correctness.

To check the correctness of selection, Alice checks the following condition for all selections (of the form $A_j = a_j$, where a_j is a constant) performed by the query: $\forall i$, if $\Phi(A_j^i) = hash(a_j||S_{i,j})$ then tuple *i* is present in the result set. Additionally, she needs to verify that for the tuples re-set. Additionally, she needs to verify that for the tuples returned in response to the query, the signature $S_{i,j}$ matches the signature of Bob. This can be verified by using Bob's public key e. public key e.

If the value of salt $S_{i,j}$ is chosen to be $h_k(A_j^i)$ (similar to α -correctness), it is possible for Bob to actually return two (or more) different sets of answers in response to a single (or more) different sets of answers in response to a single selection query and provide a correctness proof for each of selection query and provide a correctness proof for each of them. This is against our assumptions where we want Bob them. This is against our assumptions where we want Bob to commit to exactly one state of the database. This attack to commit to exactly one state of the database. This attack is possible because Bob may choose to use different keys is possible because Bob may choose to use different keys for the hash function instead of using just one key for all for the hash function instead of using just one key for all the tuples in the database (as required by the the protocol). the tuples in the database (as required by the the protocol). Defining $S_{i,j}$ as Bob's digital signature on attribute value and later verifying it at Alice's end prevents this problem. and later verifying it at Alice's end prevents this problem.

To verify if the join was performed correctly, Alice To verify if the join was performed correctly, Alice checks the following for attributes (say A_j) of joined tables: $\forall i_1, i_2 = 1, 2, \ldots, n$ if $\Phi(A_j^{i_1}) = \Phi(A_j^{i_2})$ then tuples i_1 and i_2 are included in the result.

Our solution for α and β correctness requires Bob to send $2|D|$ (root nodes of two trees per table) hashes during the proof sending phase, where $|D|$ is the number of tables in the database. These hashes can be easily combined into in the database. These hashes can be easily combined into one hash to reduce the proof size at the cost of one extra level in all authentication paths. level in all authentication paths.

6 Implementation 6 **Implementation**

We have implemented our proposed solution in Post-We have implemented our proposed solution in PostgreSQL [12]. The algorithms for generating hash trees over greSQL [12). The algorithms for generating hash trees over the database were implemented in PL/pgSQL. We used the implementation of the hash function SHA-1 from OpenSSL implementation of the hash function SHA-l from OpenSSL crypto library [14] for our experiments. The database has crypto library [14] for our experiments. The database has been extended to allow the owner to freeze data values been extended to allow the owner to freeze data values by generating proofs, and also supporting authentication by generating proofs, and also supporting authentication of query results. In our implementation, the timing of the of query results. In our implementation, the timing of the freezing can also be controlled by the querier. Whenever freezing can also be controlled by the querier. Whenever the querier wants the database to freeze its values, it is-the querier wants the database to freeze its values, it issues a send₋proof command to the database. On receiving the send_proof command the database sends a single hash value to the querier. If the querier wants to verify the results, value to the querier. Ifthe querier wants to verify the results, it issues a send-verify command to the database. On receipt it issues a send_verify command to the database. On receipt of send_verify the database returns the authentication paths for all tuples in the query result being verified. For simplic-for all tuples in the query result being verified. For simplicity, we have implemented an append-only database. But its ity, we have implemented an append-only database. But its relatively easy to extend it for general databases. In partic-relatively easy to extend it for general databases. In particular, we have to write an update trigger to update the hash ular, we have to write an update trigger to update the hash tree whenever data in a node is modified. We implement tree whenever data in a node is modified. We implement Solution 5 (α and β).

The hash trees can be generated over the tuples to be The hash trees can be generated over the tuples to be frozen when the send_proof command is received by the database. However, this approach will have a large over-database. However, this approach will have a large head on receipt of send-proof. A better alternative will be head on receipt of send_proof. A better alternative will be to generate the tree as tuples are added to the database. This to generate the tree as tuples are added to the database. This approach distributes the load evenly during the database up-approach distributes the load evenly during the database dates. dates.

For generating and storing the tree, we add the following For generating and storing the tree, we add the following For generating and storting the tree, we add the following tables to the database. We create a new table $-$ hash_tree $(node_id,phi,parent)$ to store the generated hash tree. In this tree representation, the ordering of the child nodes is this tree representation, the ordering of the child nodes is not explicit. For a given parent node, the child nodes are not explicit. For a given parent node, the child nodes are implicitly ordered by increasing node ids. For example, the implicitly ordered by increasing node ids. For example, the child with lowest node id is considered as the leftmost child. child with lowest node id is considered as the leftmost child. A global counter (count) is used to obtain new node_id values. The schema of each original table in the database is ues. The schema of each original table in the database is modified to add a new attribute called $node_id$. A temporary table, *height_table(height, node_id)* is also created.

Upon insertion of a new tuple into the database, the Upon insertion of a new tuple into the database, the add-node algorithm (refer Figure 6) is executed (by means add_node algorithm (refer Figure 6) is executed (by means of a trigger). By means of the add_node algorithm, a forest of partial merkle trees over the current rows of the forest of partial merkle trees over the current rows of the database is constantly maintained. The roots of such trees database is constantly maintained. The roots of such trees are stored in a temporary table, height_table. On receipt of a send-proof (Figure 7) request, the database merges these a send_proof (Figure 7) request, the database merges these partial trees into one tree and returns the root of this tree as partial trees into one tree and returns the root of this tree as the proof. the proof.

After the send-proof algorithm is executed, the database After the send_proof algorithm is executed, the database has a complete merkle tree over the database. Given this has a complete merkle tree over the database. Given this merkle tree, send_verify algorithm is easy. For each tuple in the result, the database returns an authentication path ple in the result, the database returns an authentication path with the help of the hash_tree table. Note that the authentication paths of these tuples will overlap and this can be tication paths of these tuples will overlap and this can be used to further reduce the size of verification data. The used to further reduce the size of verification data. The querier on receipt of this authentication path calculates the querier on receipt of this authentication path calculates the hashes and traces back the authentication path to the root hashes and traces back the authentication path to the root

in the add-node and send-proof algorithms. We only need in the add_node and send_proof algorithms. We only need the root of the partial trees generated. We can easily ignore the root of the partial trees generated. We can easily ignore the *hash_tree* table and store the hashes of trees at height *h* in the *height_table* (note that there can be only one tree at height h). This reduces the space overhead tremendously, but the ready-made merkle tree over the database will not be but the ready-made merkle tree over the database will not be available when executing the send-verification-data algo-available when executing the send_verification_data algorithm. Thus, before executing this algorithm the merkle tree rithm. Thus, before executing this algorithm the merkle tree that was used to generate the proof will need to be recreated. that was used to generate the proof will need to be recreated. This increases the time complexity of the send verification This increases the time complexity of the send verification algorithm. algorithm.

Further, we did not consider the situation when the Further, we did not consider the situation when the querier asks for proof more then once (or maybe periodi-querier asks for proof more then once (or maybe cally). In this case, we can introduce optimizations with cally). In this case, we can introduce optimizations with various space-time tradeoffs on both the database side and various space-time tradeoffs on both the database side and the querier side. Assume that the querier asks for the proofs the querier side. Assume that the querier asks for the proofs periodically, say once a day. The database now has two periodically, say once a day. The database now has two choices: (1) Bob can maintain one large merkle tree over choices: (l) Bob can maintain one *large* merkle tree over the entire database and send the root of this tree whenever the entire database and send the root of this tree whenever he needs to send the proof. In this approach, the size of he needs to send the proof. In this approach, the size of the merkle tree will gradually increase. This will increase the merkle tree will gradually increase. This will increase the amount of data that is exchanged between the two parties for proof sending and verification; or (2) The other ap-ties for proof sending and verification; or (2) The other aptres for proof sending and vermeation, or (z) in the other approach is to maintain many merkle trees – one merkle tree for each proof that Bob sends to Alice. Each merkle tree for each proof that Bob sends to Alice. Each merkle tree only covers the data that is added *after* the last proof was sent. This keeps the size of the merkle trees very small. The disadvantage is that Alice has to keep all the previous The disadvantage is that Alice has to keep all the previous hashes corresponding to data on which she can possibly run a query at any future time. a query at any future time.

7 Experimental Results 7 Experimental Results

7.1 Overhead of proof generation 7.1 Overhead of proof generation

In this experiment, the overhead caused by proof In this experiment, the overhead caused by proof generation was studied. We generated a hash-tree generation was studied. We generated a hash-tree for α -correctness verification over different table sizes. The schema of the table used for this experiment is The schema of the table used for this experiment is sales(item_id, units_sold). First, tuples were inserted into the database. Then a hash tree over these tuples was gener-the database. Then a hash tree over these tuples was generated. Tuple level granularity was used while generating the ated. Tuple level granularity was used while generating the hash tree. For comparison, the time taken by the database hash tree. For comparison, the time taken by the database in inserting the tuples is also plotted along with the cost of in inserting the tuples is also plotted along with the cost of α -proof generation. Figure 8 show the results of this experiment for different table sizes. The x -axis gives the number of tuples added to the relation, and the y-axis gives the actual time taken for the insertions in seconds. This time was tual time taken for the insertions in seconds. This time was measured using the UNIX time utility. The graph shows the measured using the UNIX time utility. The graph shows the time required to insert a tuple and also the time required to time required to insert a tuple and also the time required to make necessary changes to the trees. Note that this imple-make necessary changes to the trees. Note that this implementation uses triggers for tree creation which may not be mentation uses triggers for tree creation which may not be the most efficient implementation. However, the cost of tree the most efficient implementation. However, the cost oftree maintenance is on the same order of magnitude as the cost maintenance is on the same order of magnitude as the cost of a single tuple insertion. of a single tuple insertion.

Figure 8. Overhead of proof generation Figure 8. Overhead of proof generation

The results establish that the cost of generating the *a-*The results establish that the cost of generating the aproof hash tree increases linearly with the size of database. proof hash tree increases linearly with the size of database. For small table sizes, this cost is roughly equal to the cost For small table sizes, this cost is roughly equal to the cost incurred in inserting the tuples in the database. Both these incurred in inserting the tuples in the database. Both these costs increase linearly and the tree generation cost slope is costs increase linearly and the tree generation cost slope is roughly twice of that of insertion cost. roughly twice of that of insertion cost.

For β -correctness, the experiment was run on the same table used in the above experiment. We expect the over-table used in the above experiment. We expect the overhead of generating this hash tree to be low. This is because head of generating this hash tree to be low. This is because the hash of the data tuples is already available to us (as the hash of the data tuples is already available to us (as they are calculated during α -correctness proof generation).

Secondly, because of the single level structure of this hash Secondly, because of the single level structure of this hash tree, we only need to compute one additional hash (over all tree, we only need to compute one additional hash (over all leaves) to obtain the root hash. Figure 8 presents the results leaves) to obtain the root hash. Figure 8 presents the results of this experiment. of this experiment.

Once again, we see an almost linear relationship between Once again, we see an almost linear relationship between the number of tuples in the table and the time required to the number of tuples in the table and the time required to process the insertions. The overhead for this tree is indeed process the insertions. The overhead for this tree is indeed very small compared to the time required for generating the very small compared to the time required for generating the α -correctness tree.

7.2 Amortizing proof generation cost 7.2 Amortizing proof generation cost

In the previous experiments, the hash tree generation was In the previous experiments, the hash tree generation was done lazily - after inserting a large number of tuples. It re-done lazily - after inserting a large number of tuples. It sulted in a significant overhead whenever the database is frozen. As mentioned in Section 6, the hash tree genera-frozen. As mentioned in Section 6, the hash tree tion can also be done eagerly. This results in a cost penalty tion can also be done eagerly. This results in a cost penalty during insertions to the database, but the freezing of the during insertions to the database, but the freezing of the database is quite fast. In a way, the eager approach amor-database is quite fast. In a way, the eager approach amortizes the cost of hash tree generation over insertions. tizes the cost of hash tree generation over insertions.

This experiment compares the two approaches in terms This experiment compares the two approaches in terms of α -correctness proof generation. The hashing was done at the granularity of tuples. The database was periodically at the granularity of tuples. The database was periodically frozen (after insertion of 2000 tuples). Figure 9 shows frozen (after insertion of 2000 tuples). Figure 9 shows the time taken by the two approaches as tuples were in-the time taken by the two approaches as tuples were inserted into the table. In case of lazy computation, the flat serted into the table. In case of lazy computation, the flat lines show the insertion cost. After 2000 insertions, the lines show the insertion cost. After 2000 insertions, the send_{-proof} command is sent to the database. After receiving this command the database starts computing the hash ing this command the database starts computing the hash tree. This results in a significant overhead as shown by the tree. This results in a significant overhead as shown by the vertical lines. On the other hand, in case of eager evalu-vertical lines. On the other hand, in case of eager evaluation, each tuple insertion triggers a function that partially ation, each tuple insertion triggers a function that partially computes the hash tree. This allows the database to quickly computes the hash tree. This allows the database to quickly freeze itself, whenever a **send-proof** command is received. freeze itself, whenever a send.proof command is received.

7.3 Granularity of hashing 7.3 Granularity of hashing

As explained earlier, the granularity of hashing deter-As explained earlier, the granularity of hashing mines the data exposure. While keeping a finer granular-mines the data exposure. While keeping a finer ity seems attractive, this has a performance cost associated ity seems attractive, this has a performance cost associated with it. A Authentic Third Party database publica-A Authentic Third Party database publication tion

The crucial difference between the model proposed in The crucial difference between the model proposed in this paper and the model of authentic third-party database this paper and the model of authentic third-party database publication [6] is that we do not trust the database owner publication [6] is that we do not trust the database owner to follow the proof generation algorithm honestly. Simi-to follow the proof generation algorithm honestly. Similar to our α -correctness solution, [6] uses merkle trees to generate proof of correctness. The algorithm presented in generate proof of conectness. The algorithm presented in [6] assumes that the database is sorted on the attribute on [6] assumes that the database is sorted on the attribute on which selection is performed. To ensure β -correctness it simply reveals one tuple before and after the result set. This simply reveals one tuple before and after the result set. This ensures that no tuples are missing from the result. The so-ensures that no tuples are missing from the result. The solution works because the database owner is trusted with the lution works because the database owner is trusted with the task of properly sorting the database on the selection key task of properly sorting the database on the selection key before freezing it. While this is a reasonable assumption before freezing it. While this is a reasonable assumption for third-party database publication, it does not hold for our for third-party database publication, it does not hold for our problem model. If we remove the assumption of trust on the database owner, then the solutions presented in [6] will not database owner, then the solutions presented in [6] will not work. This is explained in the following example. work. This is explained in the following example.

item_id	units sold	
	105	
2	97	
3	221	
	105	
2	0	
ς	221	

Figure 11. Example database Figure 11. Example database

Consider the example presented in Figure 1 1. Note that Consider the example presented in Figure II. Note that the database owner Bob has (maliciously) frozen two values the database owner Bob has (maliciously) frozen two values for the number of units sold for item id 2 (along with correct for the number of units sold for item id 2 (along with correct values for items 1 and 3). This scenario is quite possible values for items 1 and 3). This scenario is quite possible if Bob does not want tie down his hands completely and if Bob does not want tie down his hands completely and would like to change the quantity of item 2 sold based on would like to change the quantity of item 2 sold based on some future information. Given the query: some future information. Given the query:

$$
\Pi_{units_solid}(\sigma_{item_id=2}(T))
$$

If we use the solutions presented in [6], Bob can either re-If we use the solutions presented in [6], Bob can either report 97 or 0 and provide a proof of correctness for the same! port 97 or 0 and provide a proof of correctness for the same! In our approach, this is not possible as Bob would not be In our approach, this is not possible as Bob would not be able to prove β -correctness for this query. Hence, the previous solutions based on the model of authentic third-party vious solutions based on the model of authentic third-party database publication is not applicable to the problem presented in this paper. sented in this paper.
