(Received 10 June 2008; published 15 August 2008)

Using a sample of 2.59×10^7 $\psi(2S)$ decays collected by the CLEO-c detector, we present results of a study of χ_{cJ} ($J = 0, 1, 2$) decays into baryon-antibaryon final states. We present the world's most precise measurements of the $\chi_{cJ} \rightarrow p\bar{p}$ and $\chi_{cJ} \rightarrow \Lambda\bar{\Lambda}$ branching fractions, and the first measurements of χ_{c0} decays to other hyperons. These results illuminate the decay mechanism of the χ_c states.

DOI: [10.1103/PhysRevD.78.031101](https://doi.org/10.1103/PhysRevD.78.031101)

In the standard quark model, the χ_{cJ} ($J = 0, 1, 2$), mesons are $c\bar{c}$ states in an $L = 1$ configuration. The χ_{cJ} mesons are not produced directly in e^+e^- annihilations. However, the large branching fractions of $\psi(2S) \rightarrow \chi_{cJ}\gamma$ make e^+e^- collisions at the $\psi(2S)$ energy a very clean environment for χ_{cJ} investigation.

The available data on the decays of the χ_{cJ} mesons into baryon-antibaryon pairs has so far been very limited. The

easiest of these final states to detect and measure is $p\bar{p}$ [1]. The partial width for $\chi_{c0} \rightarrow p\bar{p}$ was originally predicted to be zero in some models due to the helicity selection rule [2]. However, this rule has long been known to be strongly violated. More recent work has concentrated on the importance of the color octet mechanism (COM), which treats the χ_c states as more than just pure $q\bar{q}$ states and incorporates octet operators in the transition matrix ele-

ments to a given final state in order to calculate two-body exclusive decay rates [3]. In particular, Wong [4] used the COM to explain the high rate of $\chi_{cJ} \rightarrow p\bar{p}$ and made predictions for $\chi_{cJ} \rightarrow \Lambda\bar{\Lambda}$. However, these predictions fell well below the low-statistics measurements from BES [5] that imply $\mathcal{B}(\chi_c \rightarrow \Lambda\bar{\Lambda})/\mathcal{B}(\chi_c \rightarrow p\bar{p}) \approx 2$ to 4 for all three χ_c states. It has since been postulated that such large ratios can be explained without using the COM, and, instead including a more detailed quark model of the daughter products [6]. However, the resulting predictions depend greatly on the details of this model, and it is clear that more experimental input is needed. In this paper, we analyze a large sample of $\psi(2S)$ decays and present results on two-body decays of the χ_{cJ} mesons into $p\bar{p}$, $\Lambda\bar{\Lambda}$, $\Sigma^0\bar{\Sigma}^0$, $\Sigma^+\bar{\Sigma}^+$, $\Xi^-\bar{\Xi}^-$, and $\Xi^0\bar{\Xi}^0$.

The data were taken by the CLEO-c detector [7] operating at the Cornell Electron Storage Ring with e^+e^- collisions at a center of mass energy corresponding to the $\psi(2S)$ mass of $3.686 \text{ GeV}/c^2$. The data correspond to an integrated luminosity of 56.3 pb^{-1} , and the total number of $\psi(2S)$ events is calculated as 2.59×10^7 , determined according to the method described in [8].

Photons were detected using the CsI crystal calorimeter [9], which has an energy resolution of 2.2% at 1 GeV, and 5% at 100 MeV. To discriminate protons from kaons and pions, we combined specific ionizations (dE/dx) measured in the drift chamber and log-likelihoods obtained from the ring-imaging Čerenkov detector (RICH) [10] to form a log-likelihood difference: $\mathcal{L}(p - \pi) = \mathcal{L}_{\text{RICH}}(p) - \mathcal{L}_{\text{RICH}}(\pi) + \sigma_{dE/dx}^2(p) - \sigma_{dE/dx}^2(\pi)$, where negative $\mathcal{L}(p - \pi)$ implies the particle is more likely to be proton than a pion. For all protons in the events, we require $\mathcal{L}(p - \pi) < 0$ and $\mathcal{L}(p - K) < 0$. This is a very efficient requirement.

We reconstruct the hyperons in the following decay modes: $\Lambda \rightarrow p\pi^-$ (branching fraction 63.9%) [1], $\Sigma^+ \rightarrow p\pi^0$ (51.6%), $\Sigma^0 \rightarrow \Lambda\gamma$ (100%), $\bar{\Xi}^- \rightarrow \Lambda\pi^- \geq (99.9\%)$, and $\bar{\Xi}^0 \rightarrow \Lambda\pi^0$ (99.5%). Our hyperon detection follows the technique explained elsewhere [11]. Briefly, to reconstruct Λ candidates, proton candidates are combined with charged tracks that are assumed to be pions. The $p\pi$ combination is required to be within 10 MeV of the known Λ mass and then is kinematically constrained to that value.

Similarly, $\bar{\Xi}^-$ candidates are built from these Λ candidates with the addition of another appropriately charged track assumed to be a pion. The $\Lambda\pi$ vertex was required to be closer to the beamspot than the Λ decay point. The Σ^0 candidates were formed from the combination of Λ candidates and a cluster of greater than 50 MeV energy detected in the crystal calorimeter, not matched to the trajectory of a charged track, and consistent in shape with that expected from a photon. The Σ^+ and $\bar{\Xi}^0$ reconstruction is complicated by the fact that we cannot use the beamspot for the point of origin of the photons. A kinematic fit is made to the hypothesis that the parent hyperon originated at the beamspot, and decayed after a positive path-length at a point taken to be the origin of the $\pi^0 \rightarrow \gamma\gamma$ decay. A requirement was placed on the χ^2 of the fit to this topology, which includes the fit to the π^0 mass from the newly found decay vertex. In all cases, hyperon candidates within 3σ of their nominal masses are considered for further analysis, and their four momenta are then constrained to the nominal hyperon mass. These kinematic constraints were sufficient to ensure that cross-feed background from real χ_{cJ} decays, for instance $\Lambda\bar{\Lambda}\pi^+\pi^-$ in the $\bar{\Xi}^-\bar{\Xi}^-$ sample, was negligible.

For events with two distinct baryon candidates, we combine the candidates into a χ_c candidate. At this stage of the analysis, the invariant mass resolution of the χ_c is around $15 \text{ MeV}/c^2$. We then search for any unused photon in the event and add that to the χ_c candidate to form a $\psi(2S)$ candidate. This $\psi(2S)$ is then kinematically constrained to the four momentum of the beam, the energy of which is calculated using the known $\psi(2S)$ mass. The momentum is nonzero due to the finite crossing angle ($\approx 3 \text{ mrad}$ per beam) in CESR. To make our final selection, we require the $\psi(2S)$ candidate to have a χ^2 of less than 25 for the 4 degrees of freedom for this fit; this requirement rejects most background combinations. This kinematic fit greatly improves the mass resolution of the χ_c candidate.

To study the efficiency and resolutions, we generated Monte Carlo samples for each χ_c into each final state using a GEANT-based detector simulation [12]. The simulated events have an angular distribution of $(1 + \alpha\cos^2\theta)$, where θ is the radiated photon angle relative to the positron beam direction, and $\alpha = 1, -1/3$, and $1/13$ for the χ_{c0}, χ_{c1} , and

TABLE I. Efficiencies (in %) obtained from analysis of Monte Carlo generated events, and yields found in the data sample.

Mode	χ_{c0}		χ_{c1}		χ_{c2}	
	Yield	Efficiency (%)	Yield	Efficiency (%)	Yield	Efficiency (%)
$p\bar{p}$	383 ± 22	62.4	141 ± 13	66.6	121 ± 12	65.5
$\Lambda\bar{\Lambda}$	131 ± 12	16.2	46.0 ± 7.2	17.1	71.0 ± 9.2	17.3
$\Sigma^0\bar{\Sigma}^0$	78 ± 10	4.1	3.8 ± 2.5	4.0	7.5 ± 3.4	4.0
$\Sigma^+\bar{\Sigma}^+$	39 ± 7	5.2	4.3 ± 2.3	5.0	4.0 ± 2.3	4.7
$\bar{\Xi}^-\bar{\Xi}^-$	95 ± 11	7.7	16.4 ± 4.3	8.2	29 ± 5	8.4
$\bar{\Xi}^0\bar{\Xi}^0$	23.3 ± 4.9	2.9	1.7 ± 1.4	2.9	2.9 ± 1.7	2.9

χ_{c2} , respectively, in accordance with expectations for an E1 transition. The efficiencies, shown in Table I, include all the relevant branching fractions [1].

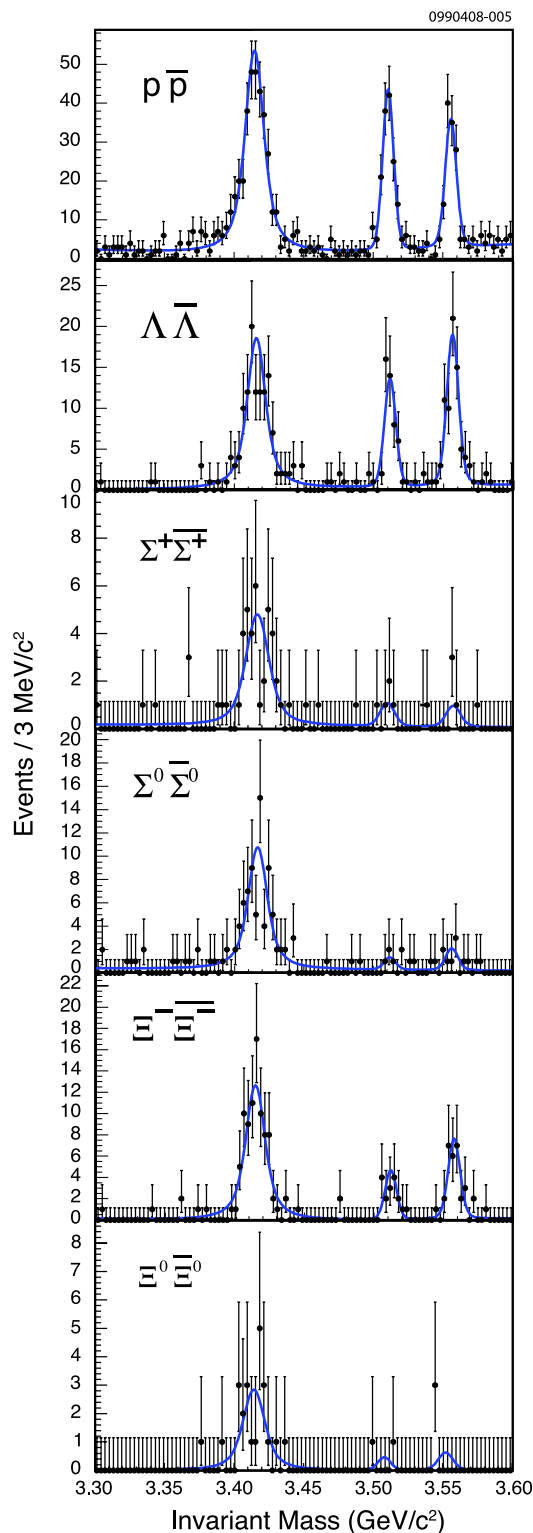

FIG. 1 (color online). Invariant mass distributions for $p\bar{p}$, $\Lambda\bar{\Lambda}$, $\Sigma^0\bar{\Sigma}^0$, $\Sigma^+\bar{\Sigma}^+$, $\Xi^-\bar{\Xi}^-$, $\Xi^0\bar{\Xi}^0$. The fits are described in the text.

The final invariant mass distributions are shown in Fig. 1. These plots are each fit with three signal shapes comprising Breit-Wigner functions convolved with Gaussian resolutions, together with a constant background term. The masses and widths of the Breit-Wigner functions were fixed according to the current averages [1], and the widths of the Gaussian resolution functions were fixed at the values found from Monte Carlo simulation (ranging from 3.6–5.1 MeV/ c^2 depending on the spin of the χ_c and the decay mode). The yields from these fits are tabulated in Table I.

To convert the yields to branching fractions, we divide by the product of the number of $\psi(2S)$ events in the data sample, the detector efficiency, and the branching fractions for $\psi(2S)$ into χ_{cJ} . For the last factor, we use the CLEO measurements of $\mathcal{B}(\psi(2S) \rightarrow \gamma\chi_{c0}) = (9.22 \pm 0.11 \pm 0.46)\%$, $\mathcal{B}(\psi(2S) \rightarrow \gamma\chi_{c1}) = (9.07 \pm 0.11 \pm 0.54)\%$, and $\mathcal{B}(\psi(2S) \rightarrow \gamma\chi_{c2}) = (9.33 \pm 0.14 \pm 0.61)\%$ [13]. The results are tabulated in Table II.

We consider systematic uncertainties from many different sources. All modes have a 2% uncertainty from the total number of $\psi(2S)$ decays [8]. The requirement on the χ^2 of the constraint to the beam four momentum has been checked by changing the cut and noting the change in the yield in these, and other similar decay modes. Based on this study, we place a systematic uncertainty of 2.5% on the efficiency of this requirement. The uncertainties due to track reconstruction are 0.3% per charged track. The limited Monte Carlo statistics introduces an uncertainty that is always a small fraction of the statistical uncertainty in the data. Using comparison of data and Monte Carlo simulation of hyperon and antihyperon yields from the $\psi(2S)$, we checked our modeling of the hyperon selection efficiency. The assigned systematic uncertainty arising from this study was up to 3% per hyperon. The systematic uncertainty due to the photon detection and shower-shape criteria is set at 2% per photon. In the case of the χ_{c1} decaying into two spin one-half particles, the two daughters can have their spins either parallel or antiparallel, and in the χ_{c2} case there are even more possibilities of combinations of intrinsic spins and relative angular momentum. These helicity correlations are not well known in the case of decays into baryons, and this introduces a small uncertainty in the modeling of the efficiencies. We investigated the effects of helicity amplitudes on our efficiency by generating Monte Carlo with a variety of different helicities and found small variations. From this study, we assign a 1% uncertainty in the efficiency of the χ_{c1} and 2.5% of the χ_{c2} . The plots are all well fit using the fitting functions described above. By studying the variation of the yields of the high statistics modes resulting from floating the signal parameters, we assign a 2% uncertainty in each mode due to uncertainties in the fitting procedure. When calculating the final branching fractions, we add the above systematic uncertainties in quadrature. The uncertainty due to the

TABLE II. Branching fraction results (in units of 10^{-5}) for each decay mode. The uncertainties are statistical, systematic due to this measurement, and systematic due to the $\psi(2S) \rightarrow \chi_{cJ}\gamma$ rate, respectively. The limits on the branching fractions include all systematic uncertainties.

^aThe BES central value [14] for this measurement is $(53 \pm 27 \pm 9) \times 10^{-5}$, in good agreement with this work.

$\psi(2S) \rightarrow \gamma\chi_c$ branching fractions, a small fraction of which is in common with the other uncertainties, is kept separate and quoted as a second systematic uncertainty.

For evaluating the limits in the cases where there is no significant signal, we take the probability density function and convolve this with Gaussian systematic uncertainties. We then find the branching fraction that includes 90% of the total area.

In summary, we measure branching fractions for χ_{c0} decays into $p\bar{p}$, $\Lambda\bar{\Lambda}$, $\Xi^-\bar{\Xi}^-$, $\Xi^0\bar{\Xi}^0$, $\Sigma^0\bar{\Sigma}^0$, and $\Sigma^+\bar{\Sigma}^+$. For χ_{c1} and χ_{c2} , we find significant signals and measure branching fractions into the first three of the above decay modes. Upper limits on branching fractions are obtained for the remainder of the modes. In the case of $\chi_{cJ} \rightarrow p\bar{p}$ and $\chi_{cJ} \rightarrow \Lambda\bar{\Lambda}$, these measurements are the most precise to date; in the other modes they represent first measurements. Our values of the branching fractions for $\Lambda\bar{\Lambda}$ are

below those reported by BES, but consistent with them within the errors, and they confirm the trend that the branching fractions into $\Lambda\bar{\Lambda}$ are higher than those for $p\bar{p}$. The fact that the χ_{c0} branching fractions into $\Sigma\bar{\Sigma}$ and $\Xi\bar{\Xi}$ are all greater than that of $\chi_{c0} \rightarrow p\bar{p}$, a trend not mirrored in the χ_{c1} and χ_{c2} decays, is not in agreement with naive expectations for the decay of an SU(3) singlet.

We gratefully acknowledge the effort of the CESR staff in providing us with excellent luminosity and running conditions. D. Cronin-Hennessy and A. Ryd thank the A. P. Sloan Foundation. This work was supported by the National Science Foundation, the U.S. Department of Energy, the Natural Sciences and Engineering Research Council of Canada, and the U.K. Science and Technology Facilities Council.
